The responses of simple cells used to illustrate this paper have all been recorded from the striate cortex of the cat, the cells being distinguished as a class in the following way (cf. Pettigrew et al., 1968a). They have little or, commonly, no spontaneous or maintained discharge. For this reason, they are easily missed and must be sought by the continual presentation of a stimulus, which itself is being changed continually. One hopes that, in this way, the stimulus complex specific for each cell will be tried as the cell comes within the recording range of the advancing microelectrode. The excitatory zone in the receptive field is usually very small (frequently 0.5 degree or less across), particularly when it is close to the center of gaze. The units respond best to a straight edge or contrast border with a particular angle of orientation, and moved slowly across the receptive field in a specific or preferred direction (Hubel and Wiesel, 1959, 1962). If the direction of movement of the slit departs from the optimum by about 20 degrees, the firing is markedly reduced or abolished (Figure 3F) (Campbell et al., 1968). Most frequently they respond in one direction of movement and little (Figure 3A) or not at all (Figure 2) in the opposite direction. As a stimulus, stationary spots of light flashed on and off are not so effective as a moving slit, and may be completely ineffective. The average response histogram obtained by means of a multichannel scaler is probably the simplest quantitative measure of the extent and sensitivity of the excitatory zone.

Our general experimental method may be described briefly (Pettigrew et al., 1968a; Joshua and Bishop, 1970). A cat, anesthetized (N_2O/O_2) and completely paralyzed, faces the rear-projection tangent screen, which is 2 meters in front of the animal. The striate unit is stimulated by a slit of light projected onto the back of the translucent screen by reflection from a system of two mirrors, each mounted on the coil of a moving coil galvanometer (see Figure 6B). In this way, the slit of light can be positioned readily anywhere on the screen. The slit may be varied in length, width, and orientation, and the speed and amplitude of movement are controlled precisely by applying the output of a function generator to the galvanometer coils. A pulse from the function generator at the start of a cycle sets the multichannel scaler advancing from channel to channel in step with the steadily advancing slit. As the slit passes over the excitatory zone of the receptive field, counts of the singleunit discharges are added to the appropriate bins in the scaler. The slit then passes back over the receptive field before it begins another cycle.

Figure 2 shows typical, sharply-defined, unimodal average-response histograms from a simple unit. They were produced by an optimally-orientated long narrow slit of light moved broadside forward and backward across the receptive field. The unit was highly selective in that it responded in only one direction of movement and then only to the trailing edge of the slit. The single peak progressively shifted to a later and later position on the back sweep of the histogram as the slit was widened from 9 minutes of arc to about 6 degrees (Figure 2), while the starting position of the trailing edge on the forward sweep was kept constant.

Figure 3 was prepared from another simple cell. Histogram A is the response to the movement of a slit 17 minutes of arc in width. The cell is almost completely direction selective, and the response is confined largely to a single peak on the back sweep. This peak was due to the summed effect of the responses to the leading (positive) and trailing (negative) edges of the slit as is shown by the fact that when the slit width was increased from 1 cm to 12 cm (Figure 3B), the responses to the leading (L) and trailing (T) edges were clearly separated from one another by an amount closely related to the width of the slit. As the starting position of the trailing edge was kept constant, it was easy to assign the peaks in the histogram to the appropriate edge. The nature of the organization of the receptive field center may, however, lead the relationship between slit width and response separation to be nonlinear for very narrow widths, and this effect will then persist as a constant small difference between the parameters at larger slit widths (Figure 3A and B; Henry, Bishop, and Coombs, unpublished observations).

Although still only responding to edges, various units show a range of different response patterns. Some units

FIGURE 2 Average response histograms from a simple striate unit to movements of a slit of light forward and backward across its receptive field. The arrow indicates the turnaround point. The unit responds only to movement in the backward direction and then only to the trailing edge of the slit. Successive responses are to increasing slit widths as indicated, the starting position of the trailing edge for forward movement being kept constant throughout. The graph (B) plots slit width against position of the response peak in the histogram. (Henry, Bishop, and Coombs, unpublished observations.)

respond only to one edge, either positive or negative, and then only in one direction. Others respond to one edge but in both directions of movement. Still others respond to both edges in the forward direction and only one edge in the backward sweep, and so on. Furthermore, whether a response occurs to a particular edge depends on additional factors, such as the presence or absence of other edges and their spatial relation to the edge in question.

Recently we have shown that the excitatory zones in the receptive fields of simple units are always partly enclosed by a large inhibitory surround, which is particularly intense immediately adjacent to the excitatory zone (Figure 3C and D; Henry et al., 1969, and unpublished observations). We demonstrated the inhibitory regions by using two independently controlled slits of light, moving asynchronously with respect to each other, but both at about the same optimal

FIGURE 3 A, B. Average response histograms from a simple unit to movements of a slit of light forward and backward across its receptive field. Responses to both leading and trailing edges of the slit on the backsweep are indicated by the use of slits of different width. C, D. Average response histograms from the same unit, showing how inhibitory regions in the receptive field are revealed by the use of the testing slit of light against the background of an artificially induced discharge. Dotted areas show the level of the induced discharge in the absence of the testing stimulus. The histograms are for two directions of movement of the testing stimulus: C, in the preferred direction; D, at right angles to the preferred direction. (Henry, Bishop, and Coombs, unpublished observations.)

speed. The movement of one slit (conditioning) was of small amplitude and confined to the excitatory zone of the receptive field, and the other (testing) had a large sweep that moved right across the whole of the receptive field. Whenever the conditioning stimulus moved in the preferred direction it produced a relatively high spike discharge, which, in the absence of the testing stimulus, filled the bins in the multichannel scaler fairly uniformly (Figure 3, dotted areas). The filling was uniform because the spike discharge caused by the conditioning stimulus was random with respect to the cycling of the multichannel scaler. The recycle pulse for the scaler always came from the function generator used to drive the testing stimulus, and the function generator for the conditioning stimulus operated asynchronously to it. Inhibitory regions in the receptive field are readily demonstrated against this artificially-induced maintained discharge by having the two slits, conditioning and testing, operating at the same time.

All the histograms in Figure 3 were obtained from one simple cell. The responses A and B give no indication of the presence of inhibitory regions in the receptive field. The latter were, however, clearly shown when the receptive field was mapped by the above method. The two examples, C and D, are for movements of the testing stimulus in two directions, one in the preferred direction (C) and the other at right angles to it. In sharp contrast to the excitatory zone, the intensity of the inhibitory surround is relatively independent of the direction of stimulus movement. By confining the testing stimulus to the excitatory zone, it can be shown that the surround inhibition is not an essential component in the directional selectivity for excitation (Henry, Bishop, and Coombs, unpublished observations). The stimulus movement is always least effective for excitation at right angles to the preferred direction. The excitatory zone, which has an elongated shape like the simple receptive field plots described by Hubel and Wiesel (1959, 1962), is always much smaller than the inhibitory surround (Figure 4; center 0.6 degree across, surround about 6 degrees across). In the axis of the preferred movement, the inhibitory regions are not a surround but are more in the nature of bands on each side of the excitatory center. It must be stressed that no response takes place in the surround either at light ON or light OFF; it is purely inhibitory, whatever the stimulus.

Beginnings of form discrimination

Simple units require highly specific stimulus features for their discharge. They monitor small parts of the visual field for light-dark contours or those segments of contours that fall within their receptive fields. A contour is analyzed in terms of its orientation at the particular locality, the speed

and direction of its movement, and the polarity of its contrast (i.e., light-dark or dark-light). In addition, the analysis takes into consideration the presence of more than one contour within the receptive field, as when there are slits of light or dark bars. Both facilitatory and inhibitory mechanisms contribute to this specialization. It is clear that inhibitory mechanisms suppress the activity of a cell whenever stimulus features inappropriate to its specialization are presented in the receptive field of the unit. Furthermore, at any one time, a given small part of the visual field is unlikely to provide appropriate stimuli for more than a small proportion of the cells with receptive fields in the area, so that the activity of most of them will be suppressed. A common observation is that the level of the maintained discharge of cortical units is much less than for units lower down on the visual pathway (Herz et al., 1964). Undoubtedly the inhibitory effects of inappropriate stimuli play an important part in reducing the maintained activity of cells, particularly those of the simple type.

By contrast, facilitatory effects are highly specific and must be relatively uncommon occurrences. Undoubtedly, certain combinations of appropriate stimuli, such as additional contours, boost the responses of the cell, although the operation of these facilitatory mechanisms is not so clear as is that for inhibition. The general picture that emerges is one of highly selective facilitation against a background of widespread general inhibition. The dominant theme, however, is inhibitory.

Simple receptive fields: binocular stimulus specificities

So far we have considered the properties of the receptive field for one eye. Almost without exception, however, simple units have receptive fields associated with both eyes (Henry et al., 1969), and these binocular receptive-field pairs provide the essential basis for binocular depth discrimination. Although nearly all the cells in the lateral geniculate have a binocular influence of an inhibitory nature (Sanderson et al., 1969), there is apparently no excitatory interaction between the two retinal inputs until the visual pathways come together on simple cells in the striate cortex (see Figure 6A). A very important feature of the binocular receptive fields of striate neurons is that the highly specific stimulus complex required for their discharge is always closely similar for the two eyes. The two receptive fields have the same size and arrangement, so that whatever stimulus is the most effective for one eye (in form and orientation and in direction and rate of movement) is also the most effective for the other (Hubel and Wiesel, 1962, 1965a; Barlow et al., 1967; Pettigrew et al., 1968b). Almost without exception, the only difference between the two

receptive fields, as judged by hand plotting, relates to the phenomenon of eye dominance which has been studied in detail by Hubel and Wiesel (1962, 1963, 1965a, 1965b; Wiesel and Hubel, 1963, 1965a, 1965b).

The use of binocular parallax as a basis for depth discrimination clearly requires that the cortical neurons make estimates of the parallax produced by viewing the same feature in the visual field from the separate viewpoints of the two eyes. The essential first step in binocular depth discrimination is, therefore, the selection (from the retinal images in each eye) of those separate parts that are images of the same feature in the visual field. This first step is provided by the fact that each striate neuron is discharged only when its two receptive fields, one for each eye, are presented with the same highly specific stimulus complex, so each separate part of the retinal image in one eye is accurately paired with its fellow image in the other eye. Because of eye drifts and flicks, the pairings are being continually lost and remade, as first one pair of receptive fields and then another pick up the same object feature. The next step is the assessment of the magnitude and direction of the binocular parallax between the corresponding parts of the two retinal images. This step involves the phenomenon of receptive-field disparity.

Receptive-field disparity

The concept of receptive-field disparity, which has been developed in detail elsewhere (Barlow et al., 1967; Nikara et al., 1968; Joshua and Bishop, 1970; Bishop, 1970), is illustrated in Figure 4. The receptive fields are conventionally represented as variously-shaped rectangles (cf. Bishop, 1970). Paralysis of the extraocular muscles in the cat preparation causes the eyes to assume a fixed position of slight divergence. For this reason, the two receptive fields of a binocularly activated unit are horizontally separated on the tangent screen. Let us now consider a group of binocular receptive-field pairs chosen so that all the members for the right eye have the same, but arbitrary, visual direction (Figure 4). Because they have precisely the same direction, all the right-eye fields lie accurately one on top of the other on the tangent screen. If we now look at the left-eye members of the receptive-field pairs, we can see that they are not in register but form a two-dimensional scatter to which the term "receptive field disparity" has been applied (Nikara et al., 1968). The upper part of Figure 4 is purely diagrammatic, but the histogram at A, taken from the experiments of Nikara et al. (1968), shows the actual distribution of the horizontal receptive-field disparities for a group of receptive fields within about 5 degrees of the visual axis. When the vertical dimension is taken into account, the scattergram of the receptive-field disparities for the same group is shown

in B. The distribution is approximately Gaussian, with a standard deviation of about 0.5 degree in both horizontal and vertical directions. The mean receptive-field position for the left-eye distribution may be taken as exactly corresponding to the center of the superimposed receptive fields for the right eye. Under experimental conditions, however, it has not been possible to plot a sufficient number of binocular receptive-field pairs having all the members for one eye with the same visual direction. The distribution in Figure 4B was thus obtained by moving the receptive fields for one eye to a common position and adjusting the members for the other eye by a similar amount in each case. In this way, all the receptive-field scatter has been transferred to the group for the second eye.

FIGURE 4 Diagram of the method used to obtain a quantitative measure of receptive-field disparities. A. Histogram showing actual distribution of horizontal receptive-field disparities of 54 binocular receptive-field pairs within about 5 degrees of the visual axis. B. Scattergram of the horizontal and vertical receptive-field disparities of the same units as in A. (Bishop, 1970; data for A and B from Nikara et al., 1968.)

Figure 5 has been developed from Figure 4 by a converging of the eyes, as in life, so that they fixate a point F in the plane of the tangent screen. Under these circumstances, the corresponding points for central vision in the two eyes will coincide at F, and the receptive field at the center of the left-eye distribution will fall precisely over its partner for the right eye. It can be seen, however, that the receptive fields at the periphery of the left-eye distribution fail to superimpose their partners for the right eye and do so only in planes closer to or farther away from that of the tangent screen (Figure 5, dotted receptive fields). In order to use receptive-field disparities for binocular depth discriminations, the cortical mechanisms must be able to take account not only of the amounts by which particular receptive-field pairs depart from the condition of exact correspondence, but also of the direction of the disparity.

In embryological development there is presumably a limit to the precision with which the fibers from corresponding parts of the two retinas can come together on neurons in the striate cortex. Possibly this initially random element in the fiber connections is subsequently developed into a "known" pattern of receptive-field disparities and used as a basis for binocular depth discriminations. It is shown below that the condition of exact correspondence of receptive fields is signaled in the brain by the marked facilitation of the striate-neuron discharge that occurs when the receptive fields are precisely superimposed in the plane of the stimulus. A slight departure from exact correspondence leads to mutual inhibition by the two receptive fields and to the suppression of firing by the striate neuron.

Binocular mechanisms of depth discrimination

Before describing the binocular mechanisms by which depth discriminations are made, I must refer again to our experimental methods (Pettigrew et al., 1968a, 1968b; Henry et al., 1969). Figure 6A shows the pathways from the two eyes passing independently through the lateral geniculate nucleus

FIGURE 5 Diagram of a rearrangement of the upper part of Figure 4 to indicate the way in which the phenomenon of receptive-field disparity might form the basis of a neural mechanism for binocular depth discrimination. The exactly corresponding receptive fields have been superimposed in the plane of the tangent screen. The dotted receptive fields show the planes at which the other receptive fields superimpose. F is the fixation point at which the eyes converge.

FIGURE 6 General experimental arrangement for recording from single, binocularly activated, striate neurons in cat. The animal, anesthetized (N_2O/O_2) and completely paralyzed, faces a rearprojection tangent screen 2 meters in front of it. A. Prisms before each eye serve to position the receptive fields on the translucent tangent screen. B. A slit of light projected onto the back of the screen by reflection from a mirror mounted on the coil of a moving coil galvanometer. LGN, lateral geniculate nucleus; 0Δ , zero prism diopters.

before finally coming together on neurons in the striate cortex. The divergence of the eyes due to the paralysis is overcome by means of prisms in front of each eye. In this way, the two receptive fields of a striate neuron can be moved over the tangent screen so that they come into exact correspondence, designated 0Δ (zero prism diopters) for descriptive purposes. By keeping the position of the lefteye receptive field constant and moving the right-eye field to one or the other side of this position, we can study the nature of the binocular response when the receptive fields are out of correspondence by varying amounts. When the right-eye prism is placed base out, the receptive field is moved to the right of the left-eye field and, in like manner, to the left for the base in position. Shifting the receptive fields in this way is equivalent to moving the plane of the stimulus closer to and farther away from the animal, while keeping the relative positions of the receptive fields constant, which is, of course, the situation that obtains under natural conditions.

As described above, the organization of the receptive fields of simple striate neurons includes a long, narrow, directionally selective, excitatory center and a roughly circular, nondirectionally selective surround. The term "receptive axis" has been used for the line of sight passing through the center of a receptive field of a visual neuron (Bishop et al., 1962b). By definition, therefore, the two receptive fields of a binocularly-activated neuron will superimpose in the frontoparallel plane where their receptive axes cross. The diagrams in Figure 7 show the essential features of the interaction between the receptive fields of a simple striate neuron at successive frontoparallel planes along the two receptive axes. By way of simplification, the excitatory centers of the receptive fields in Figure 7A have been given a vertical orientation, the cell responding preferentially to a horizontally moving stimulus. In this case, the centers extend over the greater part of the vertical dimension of the receptive fields, the inhibitory surrounds or side bands, drawn conventionally as ellipses, lying mainly to the left and right.

Figure 7B is a highly simplified diagram showing the average response histograms to be expected at the different frontoparallel planes as a result of the interactions between the two receptive fields. In the plane of exact correspondence, the receptive axes cross and the excitatory centers superimpose. Under these circumstances, the binocular response is markedly facilitated. Just in front of and behind this position, the receptive fields have moved out of register so that the excitatory center of each receptive field lies in the inhibitory surround of the other field. The binocular response is then greatly depressed or abolished. Still farther in front and behind, the receptive fields have become sufficiently separated for each to produce a response independently of the other.

It must be emphasized that the diagrams in Figure 7 show the interactions of the two receptive fields of a single striate neuron. The extrapolation from these ideas to concepts such as Panum's fusional area and regions for diplopia must be made on the basis of populations of striate neurons with partially shifted, reciprocally overlapping distributions of receptive-field disparities. For the one eye there are, of

FIGURE 7 Schematic diagram of the essential neural mechanisms underlying binocular single vision and stereopsis. A. Superimposition of the binocular receptive fields of a striate neuron at successive frontoparallel planes in the vicinity of the intersection of the two receptive axes. The receptive axis is the line of sight passing through the center of a receptive field. B. Schematic representation of average response

histograms, showing facilitation and depression of the binocular responses to stimuli situated at the same frontoparallel planes as the receptive fields in A. Marked facilitation occurs at the intersection of the receptive axes, and depression at positions immediately in front of and behind the intersection.

course, a large number of sets of striate neurons, such that the members of each set have receptive fields with the same visual direction, but with the visual direction varying from set to set. For the other eye, each set will have associated with it a two-dimensional distribution of receptive fields, similar to that shown in Figure 4. The separate distributions for the latter eye will be spatially offset with respect to one another in a way that closely corresponds to the spatial arrangement of the sets of receptive fields for the former eye. The above concepts have been developed more fully elsewhere (Bishop, 1970).

A rather more complicated pattern of binocular responses is usually obtained under experimental conditions even when the stimulus is a single light-dark border. The added complexities arise mainly from asymmetries both in the spatial arrangement and in the intensity of the excitatory and inhibitory areas of the two receptive fields as well as from the presence in the fields of regions of subliminal excitation. Furthermore, when slits or bars are used as stimuli, responses may occur to both leading and trailing edges.

Figure 8 shows the experimental results obtained by interacting a binocular receptive-field pair in a manner analogous to that shown in Figure 7 (Henry, Bishop, and Coombs, unpublished observations). The unit was selected for the relative simplicity of its responses, and the stimulus was a single, vertically orientated, light-dark border moved horizontally from left to right across the receptive field and then back again. Before recording began, the two receptive fields were brought into exact correspondence by means of prisms (see Figure 6A-0 Δ). Then the monocular responses were obtained first by the occlusion of one eye and then of the other (Figure 8, Right eye, Left eye). The two monocular average-response histograms show that the unit responded about equally from the two eyes and that the discharges in each case were also about equal for the two directions of stimulus movement.

The interaction of the two receptive fields was then studied by keeping the position of the left-eye receptive field constant on the tangent screen and moving the righteye receptive field from the superimposed position (0Δ) first to the left (4Δ base in) and then to the right (6Δ base out). Without changing the stimulus parameters used for the monocular histograms, we recorded a series of binocular responses by sweeping the light-dark border over the two receptive fields at successive one-diopter ($1\Delta = 0.57$ degree) steps of receptive-field separation. In order to simplify the illustration, only the portions of the histograms for the backward sweep are shown, although those for the forward sweep are quite similar. During the backward sweep, the light-dark border moved from right to left on the tangent screen. Hence the response from the right eye appears toward the end of the histogram when the location of its receptive field is to the left of the central position (i.e., prism base in).

When the receptive fields were exactly superimposed (0Δ) , the binocular response was greatly facilitated, being 84 per cent greater than the sum of the monocular responses. For positions on either side of exact correspondence the responses from the two eyes are virtually abolished. Farther again to one or the other side, the responses recover, but, although the prism steps covered a total range of 4 degrees, this was, unfortunately, still not sufficient to show the full extent of the receptive-field interaction. At the two extremes of the range, the response from one eye was still fairly depressed, while that from the other had passed through a stage of slight facilitation corresponding to peripherally situated zones of subliminal excitation in the receptive field. Despite such complication, the general pattern of binocular interaction closely resembles the schematic representation in Figure 7.

The quality of stereoscopic acuity in man suggests that the sensitivity of striate neurons to a change in binocular receptive-field alignment must be of a very high order. A striking and characteristic feature of the binocular responses of simple cells is the extremely sharp transition from facilitation to inhibition for very small shifts in binocular receptive-field alignment. The binocular responses in Figure 7 changed from maximal facilitation to almost total inhibition for a change in alignment of only about 0.5 degree (0 Δ to 1 Δ base in). The cell may well have revealed a greater sensitivity had finer prism settings been used. Other units have

sweep) of the histograms are shown. Binocular responses were recorded over a range of right-eye receptive-field positions to one (6Δ base out) and the other (4Δ base in) side of the left-eye receptive field which was held constant throughout. The full extent of the facilitated response when the fields were exactly superimposed (0Δ) is shown at the right of the column. (Henry, Bishop, and Smith, unpublished observations.)

FIGURE 8 Upper right: Monocular average-response histograms of a simple striate neuron to horizontal movements of a vertically orientated light-dark border passing across each receptive field from left to right and back again. The arrow indicates the turnaround point in each case. The responses are about equal for the two eyes and for the two directions of movement in one eye. Left column: Binocular average-response histograms for the same unit with the use of the same stimulus. Only the second halves (backward

been studied with changes in prism power as small as 0.1Δ . In one instance, the transition from the peak of facilitation (167 per cent) to complete inhibition occurred for a change in receptive-field alignment of less than 10 minutes of arc (Henry et al., 1969). The determination of the limits of the sensitivity of striate neurons for binocular depth discriminations is set by present techniques for eliminating or obviating residual eye movements.

Binocular gate neurons

Many of the cells in the striate cortex, particularly those of the simple type, are reported to be exclusively monocular and without influence from the other eye (Hubel and Wiesel, 1962, 1968). Recently, however, Henry et al. (1969) have shown, in the cat, at least, that many, if not most, of these monocularly discharged simple cells have powerful inhibitory and subliminal excitatory receptive fields for the nondominant eye. This new kind of receptive field has been revealed against the background of an artificially induced maintained discharge, with the use of a technique similar to that described above for demonstrating inhibitory regions in the receptive field of the dominant eye. Although discharged from only one eye, these simple cells, it has been suggested, act as binocular gate neurons (Bishop, 1970). In the binocular situation they allow the

discharge of the cell only when the specific stimulus is at the precise depth in space at which the subliminal excitatory region in the field of the nondominant eye corresponds with the excitatory region for the other eye (Figure 9). The binocular gate mechanism is shown diagrammatically in Figure 9. A simplified explanation can now be given in neurophysiological terms. A more adequate statement calls for a detailed extrapolation from single units to neuron populations (cf. Bishop, 1970). A striate neuron will be discharged when the specific stimulus is presented at the precise depth in space where the two receptive axes cross. Binocular

BINOCULAR GATE NEURON

FIGURE 9 Diagrammatic representation of the interaction between the receptive fields of a binocular gate neuron. With monocular stimulation, the unit is discharged only from the left (dominant) eye, but, when the optimal stimulus is applied monocularly to the small central region of the receptive field of the nondominant eye, the excitatory state of the cell is raised above the resting, but below the firing, level. In the binocular situation, the critical depth for firing occurs where the receptive axes cross, because the

Binocular single vision and stereopsis

The study of receptive-field disparities in the paracentral visual field has provided a definition of the horopter in neurophysiological terms and has led to the development of a construction analogous to Panum's fusional area (Joshua and Bishop, 1970). The detailed application of this new knowledge to the problems of binocular single vision and stereopsis has been considered elsewhere (Bishop, 1970). Figures 7 and 8, however, provide the opportunity for referring briefly to the solution of one of the hitherto unresolved key problems. There have long been difficulties associated with any simple concept of corresponding retinal points as a basis for binocular single vision and stereopsis. Binocular depth perception entails the stimulation of horizontally disparate retinal elements by a single object point, yet the ultimate percept is that of a single object point. How can single vision arise from the stimulation both of corresponding retinal points and of noncorresponding retinal points?

liminal and subliminal excitatory regions of the two receptive fields coincide at this point. Small misalignments of the receptive fields, either in front of or behind the critical depth, lead to mutual inhibition. Under monocular stimulating conditions, the discharge from the dominant eye would not, of course, be subject to this inhibitory influence, and the cell would fire much as it does when stimulated binocularly at the critical depth.

single vision results from the simultaneous stimulation of the two receptive fields, and the depth assessment that is made will depend on the receptive-field disparity of the neuron concerned (Figure 4). Double vision results from the successive stimulation of the two receptive fields, which is to be expected when the stimulus is presented in a plane either nearer to the animal or farther from the site where the receptive axes cross. Double vision in the immediate vicinity of the crossing point is prevented, however, by the mutual inhibition exerted by the two receptive fields. This effect is doubtless related to the phenomenon of obligatory single vision that obtains within Panum's fusional area. Figure 7 shows that diplopia will nevertheless occur when the plane of the stimulus departs still farther from the specific depth for binocular facilitation. The two receptive fields then become sufficiently separate for their successive stimulation to escape mutual inhibition. In man, when single objects are observed outside Panum's fusional area, diplopia occurs, although a measure of stereoscopic experience still persists for a short space both in front of and behind

the area. It is postulated that diplopia results when the majority of binocular receptive-field pairs are stimulated successively, although some depth discrimination may still be possible in the face of the diplopia if a significant population of binocular receptive fields remains with sufficient disparity to be stimulated simultaneously (Bishop, 1970).

Higher-level discrimination

It is beyond the scope of the present paper to consider what is known of the subsequent stages in the discrimination of form by the higher-order cells, both in the striate cortex itself and in the parastriate area (cf. Hubel and Wiesel, 1965a), but brief mention is made of the role that complex cells may play at a higher level by generalizing the binocular depth specificities of simple cells (Pettigrew et al., 1968b).

Complex units: specificities and generalization

Complex receptive fields have been distinguished in the following way (Pettigrew et al., 1968a). The neurons concerned generally have a fairly brisk spontaneous activity, and their receptive fields are relatively large-generally more than 3 degrees across. The response to moving contours is highly directionally selective, and the discharge is of relatively high frequency and well maintained. The average response histograms are complex and multimodal in form. An important characteristic of this type of receptive field is that very small amplitude movement, much smaller than the field dimensions, of a slit or line stimulus will produce a response, provided the orientation and direction of movement are not too far from optimal. The direction of movement and orientation of the slit are important, but the exact position within the receptive field is not. In other words, the unit has specificity for movement in a particular direction, but has generalization for position (i.e., visual direction), and commonly this generalization also extends to the sign of the contrast edge (i.e., whether positive or negative).

Hubel and Wiesel (1962) have suggested that the properties of complex units are derived from pooling the outputs of a number of simple units, all of which have the same directional selectivity for movement, and our work suggests that there may, in turn, be directionally selective subunits even within the small fields of these simple-cell components (Pettigrew et al., 1968a).

Figure 10 shows the binocular responses of a complex unit to a precisely oriented slit moved in the preferred

FIGURE 10 Binocular interaction on a complex unit with its receptive fields in varying degrees of noncorrespondence to show the narrow range of facilitation despite large receptive-field size. The receptive fields are represented by rectangles in the lower portion of the graph, and the relative positions of the IPSI (unbroken outlines) and CONTRA (broken outlines) receptive fields are shown at contralateral prism settings of 2Δ up, 1Δ up, 0Δ and 1Δ down. The receptive fields were quite large, measuring 6 degrees across. The histograms show responses to movement of a slit stimulus (3 degrees \times 0.2 degree) in the preferred direction across the monocular (lower right: IPSI and CONTRA) and across both receptive fields at different prism settings on the contralateral eye. Horizontal broken lines indicate the amplitudes of the separate monocular responses; the two monocular average-response histograms are shown at the extreme right. The graph shows mean evoked response as a function of prism setting. The ipsilateral eye was dominant. (From Pettigrew et al., 1968b.) direction across the length of the two receptive fields, both when they were in exact correspondence and also when in varying degrees of nonalignment (Pettigrew et al., 1968b).

When the receptive fields were out of correspondence by little more than 1 degree ($2\Delta = 1.1$ degree), the binocular response fell close to or below the level for the nondominant eye, and would doubtless have fallen still farther had tests been made at greater receptive-field separations. In other words, the two receptive fields had to be moved out of alignment by only about one-sixth of their length to produce marked depression of the binocular response. They would, of course, have been able to discriminate disparities that were much smaller than 1 degree. The specificity of some complex units for a narrow range of binocular disparities may therefore be comparable with that found in the case of simple units.

If we again consider the complex unit having as input a number of simple cells, all with the same directional selectivity, we must now suppose that the input cells may also have receptive fields with the same (or very nearly the same) binocular correspondence. Thus, we may suppose that there has been a pooling of units, all of which have the same directional selectivity and the same binocular discrimination with respect to depth. Under natural conditions, such a unit would be optimally activated by a line stimulus over a relatively wide range of visual directions (6 degrees for the unit in Figure 10) but only over a much narrower range of depth in space. Depth discrimination would be generalized for visual direction and probably also for contrast. The selectivity for depth discrimination is again achieved by binocular facilitation for the optimal stimulus when it is presented at the depth in space at which the receptive fields correspond and by mutual inhibition for stimuli at other than the preferred depth.

Conclusion

The beginnings I have described have not taken us very far toward an understanding of the brain mechanisms by which we discriminate the visual forms of everyday life. Even the most complex cells so far studied in the higher visual areas still seem to be concerned with the elements of form rather than coherent wholes. Cells have yet to be discovered that respond only when the simplest of forms, such as a rectangle or a circle, is presented in the visual field. Of course, it may well be that the simplest forms for the particular animal are not simply geometrical. Unfortunately, we still have only a very rudimentary understanding of form discrimination in animals, using behavioral methods, and a satisfactory psychophysics of form perception has yet to be developed for man. The discrimination of form may always be the property of groups of neurons, perhaps always of large assemblies of neurons and never in any sense the trigger feature for one neuron. If such were the case, it would explain why the stimulus requirements attributed to the higher-order hypercomplex cells in Area 19 are still surprisingly simple in relation to what might have been expected from the enormous complexity of the three visual areas. It also means that the concept of a trigger feature for single neurons, as applied in the more peripheral parts of the visual pathway, may no longer be relevant in the cerebral cortex or may at least become increasingly less relevant.

Summary

The concept of a receptive field is the central idea in visual neurophysiology at the present time. The receptive field of a visual neuron is the small part of the total visual field in which the specific stimulus must be applied in order for the cell to be discharged or for that discharge to be inhibited. Recent studies of the receptive fields of single neurons in the visual cortex, particularly in the cat, have made it possible to present a detailed neurophysiological theory of binocular single vision and stereopsis for the first time. By contrast, much less progress has been made toward an understanding of the neural basis of form perception, reflecting the much greater difficulties inherent in such a task. Relative progress in these two fields depends in large measure on corresponding developments in psychophysics. The neurophysiologist studying visual mechanisms looks to psychophysics to define the nature of the stimulus and to give an account of the perceptual process. The psychophysics of binocular vision has been well developed since the nineteenth century, and important advances continue to be made, but a psychophysics of form barely exists today.

The present account of the cortical beginning of binocular depth discrimination and form vision is largely limited to a consideration of the receptive fields of simple cells in the striate cortex. Simple cells are presumed to be the stellate cells situated principally in Layer IV where they receive geniculocortical axon terminals. These cells require highly specific stimulus features for their discharge and monitor small parts of the visual field for light-dark contours or those segments of contours that fall within their receptive fields. A contour is analyzed in terms of its orientation at a particular locality, the speed and direction of its movement, and the polarity of the contrast. Both facilitatory and inhibitory mechanisms contribute to this specialization, and stimuli that are inappropriate for the particular cell lead to the inhibition of its discharge. The picture that emerges is one of highly selective facilitation against a background of widespread general inhibition. Although it may be said that simple cells are concerned with the elements of form rather than coherent wholes, such also appears to be true of the most complex cells yet studied in the higher visual areas.

Many cortical neurons have receptive fields for both eyes,

each field having the same highly specific stimulus requirements. There are, in addition, binocular stimulus specificities. At the crossing point of the lines of sight through their centers, the two receptive fields are accurately in register, one over the other. When such is the case, the stimulus that is optimal for one receptive field must also be so for the other, and the firing of the cell is greatly facilitated. At other depths, the receptive fields are out of alignment, and mutual inhibition occurs. The spatial distribution of the binocular receptive-field pairs is such that only a small proportion can exactly correspond in the frontoparallel plane which contains the fixation point. The remainder are said to show receptive-field disparity. This concept has been developed to provide a neural mechanism for binocular single vision and stereopsis, and resolves the long-standing difficulty posed by the perception of a single object from the stimulation of disparate retinal elements.

Acknowledgments

I wish to thank my colleagues Mr. G. H. Henry and Mr. J. S. Coombs for allowing me to use unpublished data. My thanks are also due to Mrs. Eva Elekessy and Miss Isabel Sheaffe for their assistance in the preparation of this paper.

Neural Subsystems: An Interpretive Summary

LEON D. HARMON

Амвкоѕе Віексе, in his *The Devil's Dictionary*, defined mind as follows:

Mind, n.—A mysterious form of matter secreted by the brain. Its chief activity consists in the endeavor to ascertain its own nature, the futility of the attempt being due to the fact that it has nothing but itself to know itself with.

Perhaps Bierce's pessimism is as overemphasized as it is oversimplified, but in all truth we are obliged to face up to some staggering problems now that neurophysiology is emerging from its naive infancy. Because the problems range from molecular to behavioral, we may find it useful to ask a rather curious question: What exactly do we mean by saying we wish to "understand" the brain? There are several different answers, descriptions, and models, each capable of being true, but each profoundly different.

Consider an analogy couched in computer terms. I shall give you a desert island and on it place a high-speed digital computer, complete with terminal equipment. I shall keep it in good repair indefinitely, through any trauma you impose. Your task is to "understand" that system. My conditions are that you may import any number of people of any discipline, any knowledge, except that they must know nothing *a priori* about computer theory, structure, or function.

You are to obtain "understanding" in three different ways. First, one of your teams must find out how to operate the computer; they must discern its gross input/output functions. They will convince me of their "understanding" when they are able to write a complete programing manual for the system.

Another group must seek understanding at a quite different level. They are required to find out, for instance, what a shift register is and how an adder works. This group will convince me of their understanding when they are able to design a similar machine—not identical, but using the same principles of subsystem organization, operation, and interaction.

A still different level of "understanding" must be provided by the third group. It is required that they find out how the elemental components operate. They must, for example, discern how a transistor works, elucidate the properties of electronic tubes, and find out about magnetic storage. They will convince me of their "understanding" when they are able to produce complete equivalent-circuit diagrams of all components, both active and passive.

Now, the conclusion at each of these three levels of understanding will be perfectly true and yet very different. That is, there are several distinct yet equally valid kinds of understanding, depending on one's domain of discourse. How well can relations be seen among these various conclusions? To begin with, it is difficult to see how understanding at one level helps that at another. For example, those persons who wish to understand at the programingmanual level could not care less whether the system uses tubes or transistors. Those who are trying to understand at the subsystem circuit level (adders and shift registers, for instance) need know nothing about programing languages or pattern-recognition algorithms. And those who wish to understand how a transistor functions are not helped either by adder theory or by Fortran IV.

Of course, there are logical and causal relationships among all three levels, but in this computer analogy, at any event, there seems to be little useful extrapolation from one level to another. At the very least, the ease of extrapolation is markedly direction-sensitive. For instance, it appears unlikely that any knowledge of the structure or function of an adder can lead to an understanding of a pattern-recognition operation, because the adder is the same whether the computer is calculating π , is recognizing a geometric figure, or is composing a fugue. Similarly, in neurophysiology, it seems equally hopeless to accept the standard argument that one must start at the lowest levels (e.g., molecular, subcellular), opening *all* black boxes before going on to greater system complexity.

Extrapolation in the other direction may, however, be somewhat easier. Knowledge at a higher level may help one develop strategy for investigation at a lower level. For example, if one knows something about the process involved in a computer's pattern-recognition algorithm, there is *some* chance of deducing the role of an adder (which may be required to execute that process).

The difference is primarily one of hierarchical levels of

LEON D. HARMON Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey

code and language. That is, the descriptions of information flow and process are entirely different at these various levels; the simpler (lower level) signal structures do not yield a prediction of those at higher levels. Here is an example of wholes being not only greater than but quite different from the parts that constitute them. Furthermore, there is a matter of nonuniqueness. An adder may play a role in an infinite number of higher-order processes, whereas a size-invariant, triangle-recognition processor may have only a limited kind and number of underlying logical and arithmetical operators. Extrapolation from low level to high level diverges, but that from high to low converges.

Another kind of difficulty in coming to an understanding of nervous systems is that we may be conditioned into thinking about them in ways that are more constrained than we like to admit or are sufficiently aware of. Such concepts as serial computation, discrete subsystems, Aristotelian logic, and coding theory may well be forcing us to view, say, neocortical function in lights that are wholly inappropriate.

Subsystems

The positions taken by the contributors to this section of this book are closest to level two of the computer analogy. Neural subsystems, i.e., small nets of neurons, can be likened to shift registers and adders. We wish to understand the functions of a relatively complicated cooperative ensemble (network) of working devices (neurons), in which the signal-processing properties of the ensemble can be clearly and specifically determined. Furthermore, we wish to understand the operationally significant relationships among such subsystems, i.e., the functional organization of the entire system. Thus, the emphasis here is on *function* rather than on *structure* or on *signal codes*.

There are many kinds and numbers of subsystems in a human being; for example, there are several hundred thousand different kinds of molecules with their replicating mechanisms, thousands of metabolic subsystems, and perhaps two or three thousand neural subsystems. We shall be concerned only with several of the latter (both in man and in lower animals), as they are involved in particular processing of input (sensory), central, and output (motor) signals.

It is necessary to point out that in nervous-system analysis, the idea of "subsystems" may be misleading or even fallacious. Neural systems may be holistic to the extent that subsystem subdivision is arbitrary and useless; despite observed specificities of some gross tracts or particular nets, perhaps the mammalian CNS operates as an entity according to information-processing principles that we do not even suspect at present.

The two distinctions between *circuits* and *systems* that Lewis (this volume) has drawn have considerable importance, both conceptually and practically, for neurophysiological research. Because their implications bear strongly on the ensuing discussion, I first restate them in slightly different form.

Lewis defines a circuit as a collection of interacting elements, no subgroup of which can readily be analyzed to disclose separation of cause (input) and effect (output). This is a matter of orientation; in general, circuits are not unambiguously oriented; input and output terminals are ambiguous with respect to underlying organization. In contrast, systems (entire organisms) usually contain subgroups which have inputs that can be differentiated from outputs; this permits specification of cause and effect and hence facilitates analysis. The latter subgroups are called *subsystems*—the subject of this section of the book.

The second distinction is that of structural context. Lewis raises the troublesome question of whether neurons (or possibly even subsystems) can, in general, be considered in isolation. Owing to profuse interconnection and widespread reciprocal interaction, many of the measured properties of a system are likely to be determined ultimately by the entire system and are not uniquely and unequivocally assignable to *individual components* (just as epistatic interaction in chromosomes demonstrates intergene influences). Consequently, in the worst case, a perturbation anywhere in the system will be reflected in reaction throughout that system. Conversely, the state and the response of an individual element are not context-free—they must ultimately reflect the states and responses of all other elements.

The elements that comprise circuits generally are embedded in a structure that has strong interactive influence on those elements, so a clear separation of element function and, hence, circuit analysis is impossible unless complete structural context is taken into account. Properties of a circuit cannot be attributed to individual, particular elements. On the other hand, subsystems are by definition structurally (hence functionally) isolable; although they may be surrounded by other subsystems, that context need not be taken into account.

In what follows we define element, circuit, subsystem, and system by example and in terms of orientation and context. Elements (such as neurons) are interconnected into circuits (such as neural nets); one or more circuits forms a subsystem (such as a ganglion); one or more subsystems forms a system—perhaps an entire organism. Thus we might view a retinal bipolar cell as an element, a bipolaramacrine-ganglion cell network as a circuit, and an entire retina as a subsystem.

The critical distinction between circuit and subsystem should be viewed in terms of a bounded domain which has clearly observable input and output terminals. Within that domain we have one or more circuits; interactions are profuse, and cause and effect are obscure. Thus, with respect to
input and output terminals the domain is irreducible. Outside that domain the signal flows are discernible; context can be assessed, and cause and effect can be traced. The bounded domain is a *subsystem*, is viewed as a black box, and consists of at least one *circuit*. We refer to the domain either as a subsystem or as a circuit, depending on whether it is being viewed from outside or inside.

In the light of Lewis's observations on the immense difficulty of coming to an understanding of such a relatively small circuit as the nine-cell cardiac ganglion of the lobster, I wonder whether it is profitable to continue to seek the full internal (circuit) analysis of such a subsystem. Again the question arises-How far down in level must black boxes be opened in order to comprehend a system? One class of answer to that question, although addressed to a higher level of organization than our subsystem level, uses controlsystem analytic techniques. Such systems as eye tracking (Stark et al., 1962; Fender, 1964), pupillary servomechanisms (Stark and Sherman, 1957), and optokinetic orienting (Reichardt, 1961) have been elucidated by the identification of larger units of organization that might correspond to collections of subsystems. In this work, the black boxes are control-system functional operators such as multipliers, coincidence gates, function generators, and the like. Each is taken to subsume many neurons in networks which intrinsically are of no concern to the analysis. These are formal equivalents that are sufficiently representative and accurate for precise predictions of response in the living system to be obtained. This work has led to important and revealing results at a level of inquiry including organism behavior itself.

Because circuit analysis implies total commitment to analysis of *all* components and their interactions, the commitment may be as futile as it is irrelevant. However, if the goal is to understand *circuits* and *components* as such, and there is no hope of elucidating systems, then I would argue that such effort is justified and of great interest, simply in the investigation of nature. But if one's goal is to understand *systems* as such, then in all likelihood approaches that lie at levels between irreducible subsystems (such as the lobster cardiac ganglion) and reducible control systems (such as optokinetic supersystems) hold the most hope for meaningful neurophysiological research.

Teleology

Teleology, taken here *solely* to mean mechanical determinism, plays an important part in the analysis of living systems. Inference about role is essential, not merely tolerable, for both circuit analysis and subsystem analysis. Consider, for instance, an electronic circuit of which the orientation has somehow been established and for which even the transfer function is obtained. Simply possessing the transfer function alone is virtually meaningless without knowledge of the circuit's role *and* of normal input signals, as an infinite number of forcing functions (and therefore of input-output pairs) are possible. Such a situation is equivalent to having a differential equation without having any boundary conditions. Even the best of electrical-circuit engineers, given a schematic of modest proportions and no clue as to intended function, will be unable to assign a meaningful role to that circuit. He will remain in essential ignorance of its functional significance unless he knows what was in the designer's mind. Induction of role from form is, in general, impossible.

It simply is not enough to be able to describe a circuit and its component action, however completely, in order to comprehend its role. Suppose, for example, we assume that genetic instructions completely and unequivocally specify some particular neural system, structure, codes, and all. We shall assume a completely causal chain—all principles and mechanisms of the subsystem are absolutely contained in the genetic structure. I suspect that you may examine, test, describe, and catalogue everything about that genetic system, yet you will *not* be able to extrapolate to the implicit subsystem *unless* you also know the role and principles underlying the genetic system and its transforms.

A teleological approach in neurophysiology seems essential and should have high priority. Because of the impossibility of inferring function from form, some *a priori* prejudice as to role is mandatory. Furthermore, systems analysis may reveal *n* disjoint parameters. Because there are 2^n possible subsets, complete assessment is virtually impossible if *n* is large. One must apply criteria such as teleological constraints to narrow the possibilities. Consequently, the most revealing and significant experiments may be expected to be those in which some prior notion of operational detail (e.g., gating, filtering, and so on) is imposed.

Principles of function

An implicit assumption, distributed throughout the foregoing discussion, is that principles of neural action do or must resemble those of our machines. Consider, for example, the prevalence of contemporary opinion that nervous systems, being information processors, can be viewed as computer-like devices. It is clear that many aspects of our engineering technology are found in physiological measurements. Such properties as triggering, gating, switching, and synchronizing have been found. Amplitude discrimination, filtering, amplification, linear-to-logarithmic signal transformation, and waveform generation have been seen. The basic arithmetical operations have been documented in nervous-system responses, as have integration, differentiation, sign inversion, and correlation. In addition, there is evidence for counting, coincidence detection, delay, phase shift, and duration measurement.

Although these properties can be found experimentally, it has yet to be demonstrated that systems use them in going about their business. An especially striking example is found in Wilson's analysis (this volume) of wing-muscle stretch receptors in the grasshopper. Those units precisely encode wing-beat frequency, phase, and amplitude, yet the axonimpulse time, rate, and number that code that information are subsequently smeared out to give the CNS only a *gross* command relating to over-all average wing-beat rate and power. Here is a simple example of the danger of assessing information, code, or notion of relevant processing until and unless one knows something about, as Wilson neatly puts it, "the natural reader of that code." To correlate is not necessarily to elucidate.

Despite such seemingly negative comment, there is no reason at present not to consider neural subsystems in engineering terms. In fact, theoretical studies guiding experimental probes for subsystem operation may contribute entirely new concepts in information processing. It is perhaps not too wild a speculation that actual principles of nervous-system operation may be different, perhaps far different, from those of our present computer technology. Certainly such a difference obtains for associative memory, for example. To suspect, to look for, and perhaps to find such new principles constitute one of the most exciting problem areas of living-system analysis.

Special-purpose vs. general-purpose systems

In considering identification, measurement, and analysis of subsystems, we run into an old problem that takes on new significance for understanding at this level. It has to do with network plasticity—whether we are dealing with a network that is rigidly fixed or one that is in some manner adaptable.

Another way to speak of plasticity is to ask whether a system is "special purpose" or "general purpose," in the sense of computers. Is a particular animal special-purpose in that it is inflexible, more or less completely preprogramed, and therefore constructed with a great a priori response specificity, or is it general purpose in being capable of considerable modification of internal structure and external behavior? At least in the domain of computers, a special-purpose machine that has fixed structure (wiring) and fixed function may be much easier to analyze than is a generalpurpose machine the very "structure" (signal-flow paths) of which is infinitely modifiable by programs and by states of its memory cells. Because of such distinctions, the ways of thinking about the two kinds of systems differ considerably, as it must also be for living systems. Grasshopper and man would appear to lie at extremes of a spectrum ranging from special-purpose to general-purpose systems, and the required conceptual approaches to system analysis might differ as much as do the analyses required for understanding a typewriter and a computer.

Of course, to what extent man is a general-purpose system may be questioned. Clearly, many of his subsystems are special purpose, genetically determined, homeostatic, and quite inflexible. To the extent that there is fixed wiring and fixed processing we can proceed with greater ease and, indeed, even afford to take teleological approaches. Experiment and analysis guided by *a priori* consideration of what an animal does and needs to know have paid off handsomely (Maturana et al., 1960; Hubel and Wiesel, 1962; Nikara et al., 1968).

Command and control

A topic closely related to that of special-purpose machinery is the complex neuromuscular sequence that is activated by simple "command" stimuli. Wilson (this volume) cites a considerable body of evidence in invertebrates, particularly of genetically preprogramed structures and functions in arthropod ganglia. He holds that there are three principal classes: sensory filters, closed-loop reflexes, and pattern generators.

Such preprogramed subsystems epitomize the idea of special-purpose neural machinery. Here are structures specifically arranged to execute particular functions; presumably they are immutable, and any possible overlay of learning apparently is minimal or nonexistent (at least for simple behavior, like locomotion).

Because the ultimate business of virtually all CNS processing is to generate motor-command signals, questions pertaining to behavioral control via neuromuscular activating systems are of fundamental importance. William James, in 1897, had a remarkably modern view of this point regarding the significance of motor output when he observed: "The structural unit of the nervous system is in fact a triad, neither of whose elements has any independent existence. The sensory impression exists only for the sake of awaking the central process of reflection, and the central process of reflection exists only for the sake of calling forth the final act. All action is thus re-action upon the outer world; and the middle stage of consideration or contemplation or thinking is only a place of transit, the bottom of a loop, both of whose ends have their point of application in the outer world. If it should ever have no roots in the outer world, if it should ever happen that it led to no active measures, it would fail of its essential function, and would have to be considered either pathological or abortive. The current of life which runs in at our eyes or ears is meant to run out at our hands, feet or lips. The only use of the thoughts it occasions while inside is to determine its direction to whichever of these organs shall, on the whole, under the circumstances actually present, act in the way most propitious to our welfare" (James, 1897, *in* Gibson, 1962).

One of the rather striking generalities of pattern generation in insect motor-control systems is that stereotyped signal sequences appear to be produced from unpatterned stimuli (e.g., random pulse trains), or they may even be spontaneously generated. Wilson's description of the behavior of a central, pattern-generated, flight-control subsystem in the grasshopper illustrates the point. In that example, four subsets of phased, synchronized, motor-neuron volleys arise from relatively simple, unpatterned, central control. Although the known motor-neuron interactions appear to be too weak to account for the synchrony, the preservation of precise coordination among the four sets of wing motor neurons that have an imprecise, common, central-control input seems to argue for a mechanism (as yet unknown) whereby undifferentiated CNS signals set in motion highly precise, peripheral, temporal-pattern sequences.

The ability of a subsystem to generate intricate patterned outputs or complex motor sequences from relatively simple central commands constitutes an intriguing and fairly common class of subsystem operations in invertebrates and, perhaps, in vertebrates as well. Elaborate temporal sequences of behavior, involving many sets of muscles, can be initiated by single pulses, unpatterned pulse trains, or even random stimuli. It is as though a simple command to "go!" triggers an entire subsystem into one particular behavior pattern, as is seen in "subroutines" of swimming, walking, flying, posturing, copulating, and singing.

The numbers of circuit elements in the subsystems triggered by command fibers are not known with precision, but some reasonable guesses follow: 80 motor neurons plus a probably greater number of interneurons and oscillation producers in grasshopper-flight and cricket-song subsystems; 200–300 motor neurons plus some indefinite number of interneurons for crayfish posture and swimmeret subsystems and for cockroach walking; possibly 1000 to 10,000 motor neurons and interneurons in the only known vertebrate "control fiber," the Mauthner neurons.

At least one simple but potent circuit arrangement is known to produce temporal spike-patterns—it is recurrent inhibition. One of Wilson's examples shows that phaselocked patterned discharge occurs in simple neural networks that are laterally inhibited. In such cases, the input is a relatively indifferent common stimulus. Modeling studies of reciprocally inhibiting units have demonstrated a great variety of pattern production from simple, regular stimuli (Reiss, 1962; Harmon, 1964; Harmon and Lewis, 1966).

It appears that the production of stable, intricate, temporal-output patterns by cross-inhibited single units may be of fundamental importance to "simple" neural subsystems. Interestingly, as Wilson points out, the sensory corollary (e.g., lateral recurrent inhibition in *Limulus*) also demonstrates a potent network-organization principle, this time for sensory analysis rather than for motor synthesis. (It should be noted, however, that reciprocally inhibiting *pairs* generally are associated with temporal processing such as switching or spike-pattern generation, whereas laterally inhibiting two-dimensional *networks* usually are associated with spatial image processing such as contrast sharpening or detail filtering.)

That stimulation of a single command fiber may elicit coordinated activation of half of the musculature of the entire body (as in the crayfish defense posture) seems to argue for a kind of single-neuron importance virtually unknown in vertebrate physiology. Curiously, however, there are some vertebrate experiments which at least suggest similar action. Gross electrode stimulus was observed to cause a falcon to peer at a particular corner of a room despite the animal's being turned to various different orientations (Strumwasser and Cade, 1957). The simple stimulation of the brain of a pocket-mouse initiated a prolonged sequence of rapid two-pawed stuffing of hallucinated seeds into its cheek pouches (Strumwasser and Cade, 1957). Gross squarewave shocks to the temporal cortex of man elicited complete reruns of memory sequences (Penfield and Perot, 1963).

The foregoing examples, for both invertebrate command fibers and vertebrate simple, gross stimulation, relate to involuntary stimulus/response situations. Of course, the enormously potent *ad hoc* arrangements of neural operation available to a consciously attending human permits an even more striking unleashing of complex sequences from simple stimuli. For example, the impingement of a few photons of light on a retina in a jungle at night can trigger the shouldering, aiming, and firing of a rifle—a sequence of neuromuscular events that is more complicated by orders of magnitude than the evocation of a crayfish defense posture.

No artificial excitation of precommand-fiber structures has yet stimulated a command fiber to action, probably because the required stimulus pattern is complex. For instance, the full array of inputs required for a crayfish to rear up in defense posture probably includes visual patterns, movement, exposed position (not in cave), time of day, and so on. All these must funnel down to the command unit. The subsystem coding-decoding precursors appear to be remarkably selective and fail-safe. Presumably, interposed loops or parallel, multiple processes link the visual subsystem with the command subsystem.

It is interesting to speculate that command neurons in invertebrates have a homologue in vertebrate "decision units" (if, indeed, such exist). This would be some sort of final funneling point in a high-order animal, just before divergence to effectors. Consider, for example, a vastly oversimplified example as is schematized in Figure 1. Suppose that we ask a man to raise his right arm if a particular photograph is a picture of an individual, X, who is known to him. Let me represent the situation as one in which, if, and *only if*, the appropriate sensory input occurs, some central command-and-control subsystem initiates the neuromuscular, sequence-activation signals needed to produce the required response.

In schematic form, at least, such a situation is homologous to the invertebrate sensory filter \rightarrow command fiber \rightarrow pattern-generator. The principles of subsystem coupling and of signal-coding transformations may be qualitatively similar, at least as far as we now know. Thus, in disclosing principles of nervous-system organization and hierarchical processing, studies of relatively simple nervous systems may include some helpful clues to analysis of the more complex systems. The potential "payoff" is great, because the command-and-control box of Figure 1 encloses the great unknown turn-around zone between sensory and motor systems, i.e., generalization, decision making, and, at least in some actions and animals, consciousness.

Functional inhibition

Bishop (this volume) places particular stress on the definition and role of inhibition, especially as some controversy over interpretation of receptive-field organization stems from it. Conventionally, the idea is that an ON discharge is equivalent to an excitatory influence, and an OFF discharge reflects an inhibitory one. Bishop points out that the relationships of ON/excitatory and OFF/inhibitory are neither necessary nor common.

In one modeling study of ON, OFF, and ON/OFF responses, *both* excitation and inhibition are played off in combination

against each other in just one unit to obtain these temporal responses (Harmon, 1966). In this case, excitatory postsynaptic potential (EPSP) and inhibitory postsynaptic potential (IPSP) voltage time-courses and asymptotic levels were used as variables and clearly demonstrated the nonnecessity of relationships between circuit inhibition and over-all subsystem or functional inhibition.

Bishop's point is important, particularly because inhibition in membrane action is often confused with inhibition in system action; it is essential to distinguish between circuit inhibition and functional inhibition. A notable example is seen in the commonly held view that cerebellar Purkinje cells are inhibitory, a circuit view based on the evidence of their direct output. However, from a subsystem point of view, if Purkinje axons happen to terminate on inhibitor interneurons which disinhibit particular subsystems, the effect of Purkinje activation is excitatory. Perhaps *Limulus* retinal action is the most familiar example of the importance of analysis in terms of functional inhibition rather than in terms of EPSPs.

By viewing visual receptive-field responses in terms of inhibition and excitation rather than in terms of on and OFF, Bishop shows that receptive fields of "simple" cells are largely inhibitory (having a small, central, excitatory zone), and some are completely inhibitory. It remains to be demonstrated how much the delineation and analysis of subsystem function will improve, given this "new look," but indications are that there is increased utility. For example, Bishop shows that in binocular depth discrimination, the excitatory and inhibitory effects of stimulating a receptive field in one eye have an important gating influence on the response to stimulus of a corresponding zone in the other eye, as read by a striate neuron.

FIGURE 1 Hypothetical system representing a human requested to respond manually when he sees an appropriate visual pattern. Auditory instructions, recognized and encoded, prime central command-and-control system. Sub-

sequent visual-input stimulus, recognized as sufficient, releases primed central system to evoke sequence of neuromuscular activation signals appropriate to response requested. A particularly interesting result of testing receptive fields of simple units for inhibitory effects came from the use of two simultaneous stimuli (e.g., slits of light). A conventional, preferred-direction response is obtained in a typical receptive field, while stimulation of a *direction-independent* inhibitory surround simultaneously influences that response, producing no ON or OFF transient, only inhibition.

Just as inhibition is seen to play a dominant role in visual systems, providing highly selective discrimination, so too the functional role of inhibition also should be expected to be profound in all sorts of neural subsystems, if for no other reason than to avoid continuous cataclysmic discharge. As neural circuits of reciprocal and lateral inhibition are more and more ubiquitously seen, the great potency of opposed excitatory/inhibitory functions becomes increasingly apparent (Florey, 1961; von Euler et al., 1966). It would not be surprising if an extensive theory of neural subsystem signal filters, generators, and processors is evolved in the near future, the basic development of which would rest on relatively regular structures that use simple combinations of excitation, inhibition, and their time courses.

Hierarchical processing and decision making

The concept of hierarchical processing and control appears to be a natural, efficient way to deal *in extenso* with otherwise unwieldy systems. Such is equally true in rockets, governments, and nervous systems. The discovery over the last decade of hierarchical levels of visual-data processing in many animals from insects to vertebrates has provided one of the most illuminating new chapters in neurophysiology.

In cat and monkey, for example, as one traces the effects of patterned optical signals from retina to lateral geniculate to striate cortex to higher visual cortex, the ascending hierarchy of data processing presents an orderly and impressive progression (Hubel and Wiesel, 1962; Barlow and Levick, 1965; Barlow et al., 1967; Bishop, 1969). The most striking aspect of this level-by-level processing is feature extraction. Successive hierarchies of neural actions analyze two-dimensional retinal space to represent simple aspects of shape and temporal changes of illumination, and, through spatially discrete representations of those changes, motion is also represented.

Despite such gains in our knowledge, Bishop noted that "cells have yet to be discovered which respond only when the simplest of forms, such as a rectangle or a circle, is present in the visual field." This observation leads immediately to what are perhaps the most intriguing, yet intractable, questions in all neurophysiology—those that relate to decision making, perception, and consciousness. What, for instance, is the system (subsystem) that observes lower-order subsystems and is "aware" of a complex pattern? What is the nature of the "little man" who sits on top of the hierarchical processors, observing? Although these are not precise, well-formed, or even operational queries, it is relatively easy to formulate one that is closely related and that is of central importance to the ultimate analysis of, say, the primate visual system. It is as follows:

Given that states of single neurons in striate and peristriate cortex represent primitive features of visual scenes (lines, edges, angles) and, further, that those representations are, for some cells, invariant over retinal position but are constrained with respect to motional aspects (direction, velocity), where, how, and by what are higher-order classification responses made? An enormous amount of visual brain has so far been required to discern these relatively simple features. Where does one look next—and how? After area 19, where?

There seem to be two major possibilities. One is that other, higher structures combine the computational results of the striate/peristriate subsystem to produce these sophisticated operations we seek. The infratemporal cortex might seem to be a reasonable candidate; however, in that case, one is faced with the curious possibility that a relatively small processor (compared with everything prior, from retina to area 19) does most of the incredibly complex integrative work. The other alternative is that the modus operandi changes; single units no longer are used to represent feature states. Instead, simultaneous, combined (not statistically smeared but highly articulated) states of very large numbers of cells in striate and peristriate cortex conspire to represent, say, a recognizable face. That is, the representation is now multicellular, involving perhaps hundreds of thousands (or millions) of simultaneously signaling units, which, when read individually, are those discussed abovethe feature detectors. The states of the parts taken separately do not represent the whole; rather, it is the relations among them that are important, just as individual silver halide grains do not "represent" the photograph of a face, but the ensemble does. Similarly, flecks of chalk on a blackboard are individually meaningless but in relationship may represent a triangle.

Although a multistate response of a neural pool may represent a complex event of recognition, it may or may not actually constitute the conscious awareness of that recognition response. The ultimate conscious perception, attending to one thing at a time, may reside elsewhere, its neural substrate receiving as input the response of the recognition network. The question is open as to whether a single "pontifical" neuron or a large ensemble (as suggested above) is used to represent a final recognition state. We tend to be seduced into thinking in terms of "final common paths," i.e., ultimate convergence of many processes to one channel. But even a binary decision, such as the hand-raising example shown in Figure 1 or the vocal signaling "yes" in response to a recognized face, may involve huge numbers of neurons just to do the responsive signaling. Similarly, the binary recognition-decision itself may very well be represented by the multistate condition of a vast pool of units. This issue, discussed in detail by Bullock (Bullock and Horridge, 1965, p. 281 ff.), is one of the most tantalizing and difficult in all neurophysiology.

One final article of faith on this speculative point: I am not surprised to find grasshoppers absolutely dependent on the integrity of one or a few neurons, but I find it difficult to believe, especially in the face of cortical ablation and natural-attrition evidence, that in man there can be much dependence on unique cells, small groups, or local circuits.

It is tempting to conjecture that arrangements exist in which both individual units *and* the pools they comprise compute and represent significant information. For instance, single-unit feature detectors and even pontifical decision-makers might be part of a pool in which wave formation and propagation also play an essential role. Such subsystem design could reflect completely new and potent principles of functional organization. If this notion turns out to be at all valid, a rather different concept of "subsystem" must be developed. For here is the idea of a self-nested system, layered like an onion, a thing that is both parts and whole, a multilayered, hierarchical, signal processor, which, rather than being sequentially laminated and connected, is an everything-overlaid-on-everything holistic entity.

Summary

This chapter is, in part, a summary of some issues discussed in the section of this volume entitled "Neural Subsystems and Physiological Operations," and, in part, some personal responses to those and related issues. The central idea is that a "subsystem" point of view is especially useful in the analysis of nervous-system function.

The particular issues I have responded to range rather widely: subsystems, teleology, principles of function, special-purpose versus general-purpose systems, command and control, functional inhibition, and hierarchical processing and decision-making. Although these topics are more or less disparate, they are discussed with one common theme in mind: using a particular engineering point of view and level of inquiry to seek an understanding of neural function.

I mentioned above that many of these problems are of staggering complexity, both experimentally and theoretically. Let me suggest still one more difficulty—one that harks back to Bierce's worry that the mind has only itself to understand itself with. Conceivably, the complexity of the brain (its principles of organization and operation) may exceed the ability of its output portion (its conscious attention, language, logics of discourse, and analysis) to deal with it. In other words, the mental functions produced by the brain may well be very much simpler than the principles of operation of the underlying mechanisms giving rise to those functions.

Whether such worries are justified, and whether our circuit and our subsystem problems ultimately prove intractable in many cases, ultimate limitations still appear remote. With the continuing development of new technologies and new theory, the prospect for further and deeper understanding seems excellent.

Acknowledgments

I appreciate the feedback, both positive and negative, from the readers of an early draft of the manuscript. They include Theodore Bullock, chairman of this section of the book, and those participants of ISP 1969 whose ideas I maligned, and four relatively detached colleagues, Newman Guttman, Bela Julesz, R. F. Reiss, and Eric Wolman.

The Insect Eye as a Model for Analysis of Uptake, Transduction, and Processing of Optical Data in the Nervous System

WERNER E. REICHARDT

AT PRESENT, investigations in the field of sensory physiology are based on the application of three methods: anatomical and histological studies; electrophysiological microprobing; and evaluation of evoked behavioral responses.

The first method allows us to draw conclusions from a group of functional operations, which, in principle, could take place in the circuitry of the nerve-nets under consideration. Moreover, it is sometimes possible to exclude certain operations—a procedure that may result in omitting classes of possible perceptual processes.

By use of the second method, one may trace the information flux, especially in those parts of the nervous system that are, in one or two dimensions, isotropic in structure and in function, i.e., the interactions of which depend on the distance between two or more interacting neurons and not on their position. The technological difficulties of this method become formidable whenever the subsystem under consideration is nonisotropic. The third method can be applied to the analysis of functional principles of input-output relations in behavioral experiments, regardless of the structural complexities of the physical parameters of components in the system. This method, however, does not give us information about how these functional principles are realized physically and which components of the nervous structure actually are involved.

The account presented here concerns the application of the three methods to the analysis of the structure and function of the optical system of flies (*Drosophila, Musca*). Their nervous systems consist of about 10^5 to 10^6 neurons, which, in part, make up definable classes of elements that are replicated many times in an orderly way, so the principal circuitry can be worked out without identifying specific elements.

Representation of the optical surround in the photoreceptor layer of the compound eye

The compound eyes of a fly consist of individual ommatidia that are optically screened from one another by pigments. The kind of representation of the visual environment in the

WERNER E. REICHARDT Max-Planck-Institut für biologische Kybernetik, Tübingen, Germany.

layer of the photoreceptors (rhabdomeres) is determined by (1) the optics of the individual ommatidium, (2) the number and arrangement of rhabdomeres in every ommatidium, and (3) the geometry of the eye.

Figure 1 is an electron micrograph of a cross section of an individual ommatidium. It shows seven rhabdomeres arranged in a typical asymmetric pattern. It should be noted that the central rhabdomere (small cross section) is compound, consisting of two from individual retinular cells. They are aligned in such a way that the distal part belongs to one cell and the proximal part to another. The rhabdomeres are separated from one another and remain separated down the whole length of the ommatidium. Consequently, their optical axes differ, so that each rhabdomere receives light from different directions in the optical environment (Autrum and Wiedemann, 1962; Wiedemann, 1965).

FIGURE 1 Cross section through an ommatidium of *Musca*. Seven sensory cells with their attached rhabdomeric structures are shown. The diameter of each of the peripheral rhabdomeres (1-6) is about twice that of the central one (7). Rhabdomere 8 cannot be seen in the Figure, as it is situated proximal to 7. Note the different orientations of the microvilli in the different rhabdomeres. Fixation: glutaraldehye-dosmium. (From C. B. Boschek, unpublished.) Kirschfeld (1967) determined the angular distribution of the optical axes of the rhabdomeres, and found that these axes mark points in the optical surround that constitute a pattern similar to that of the distal endings of the rhabdomeres in an ommatidium, but inverted by 180°. It follows that each ommatidium acts as a small lens eye in which the image generated by the lens can be resolved by the seven (eight) rhabdomeres into seven points.

A striking feature of the angular separation of the optical axes of the rhabdomeres is that they match the ommatidial divergence angles. A point source of light in the optical surround may always be aligned with respect to the compound eye in such a way that seven (eight) rhabdomeres of seven different ommatidia receive light from a single source, as indicated in Figure 2. Consequently, as Kirschfeld (1967)

FIGURE 2 Drawing of a cross section of seven facets (*Musca*). The rhabdomeres, indicated by black dots, are shown in their typical arrangement in the upper eye region. Rhabdomeres surrounded by a circle receive light from one and the same point of the optical environment. (From Kirschfeld, 1967.)

has shown, seven (eight) rhabdomeres, each from a different ommatidium, are "looking" at one and the same point in the optical environment. Therefore, between individual points in the optical environment and individual photoreceptors of the fly's eye, a one-to-seven, not a one-to-one, relationship exists. As there are seven (eight) separate rhabdomeres per ommatidium, optical resolution of the eye should be determined by the angle $\Delta\varphi$ between the optical axes of adjacent ommatidia, not by the angles between optical axes of individual rhabdomeres. The alignment of the optical axes of rhabdomeres in different ommatidia has been demonstrated in the intact animal by the method of "antidromic" illumination (Kirschfeld and Franceschini, 1968). Light is shone into the brain of the fly through a small hole made in the head. Part of the light reaches the rhabdomeres, where it is guided to their distal endings and finally leaves the ommatidia through their dioptric systems. By this method, the rhabdomeres act as secondary radiants, the distal endings of which are imaged on the optical surround. Figure 3 shows how the radiation leaving the compound eye superimposes at different distances from the eye. At a large distance (greater than 1500μ), seven images from seven (eight) different rhabdomeres of seven different ommatidia join as described.

Angular sensitivity distributions of rhabdomeres

The fundamental optical properties of a compound eye are characterized by two parameters: 1. The divergence angle $\Delta \varphi$ between the axes of adjacent ommatidia. This angle sets the limit of optical resolution. In *Drosophila*, the mean of $\Delta \varphi$ amounts to $\overline{\Delta \varphi} = 4.6^{\circ}$; in *Musca*, to $\overline{\Delta \varphi} = 2.0^{\circ}$. 2. The angular sensitivity distributions of the photoreceptors (rhabdomeres), expressed by $\Delta \rho$, the half-width of the distribution. These distributions determine the contrast transmission from the optical environment onto the receptor layer.

Recent electrophysiological probing by Scholes (1969) on the dark-adapted eye of *Musca* have led to values of about $\Delta \rho = 2.5^{\circ}$. The data were taken in the dorsofrontal quadrant, where facet dimensions are largest and divergence angles are smallest. There is good evidence that the value of $\Delta \rho$ reported here relates to one of the peripheral retinular cells (numbers 1 to 6) and not to the central ones (numbers 7, 8). Because the sensitivity distribution of a rhabdomere is determined by the convolution of the lenslet Airy disk with the cross section of the rhabdomere ending, it is likely that the acceptance angles of cells 7 and 8 are narrower than those of cells 1 to 6 (Kirschfeld and Franceschini, 1970). Their $\Delta \rho$ is estimated to be in the order of 1.5° in *Musca*.

Spectral sensitivities of rhabdomeres

The first direct proof that photolabile pigments are present in the fly's rhabdomeres stems from microspectrophotometric measurements and their interpretations by Langer and Thorell (1966) and Langer (1966, 1967). They found two types of extinction spectra from individual rhabdomeres of *Calliphora*: one has a maximum of about 515 millimicrons (green receptor); the maximum of the other is about 470 millimicrons (blue receptor). The absorption with its maximum in the blue is associated with the central rhabdomere (number 7), whereas the absorption with its

FIGURE 3 Compound eye of *Musca* (female, intact animal) inspected microscopically under antidromic illumination. The focal plane of the microscope was adjusted at the following distances from the eye surface. Distance: $d = 1500\mu$ (A); $d = 1000\mu$ (B); $d = 500\mu$ (C); $d = 250\mu$ (D); $d = O\mu$ (E). (F) shows the so-called pseudopupil at the level of the cornea. Aperture A of the microscope objective is 0.11 ($u = 6.3^{\circ}$) in A to E, and 0.03 ($u = 1.7^{\circ}$) in F. (From Kirschfeld and Franceschini, 1968.)

maximum in the green is related to rhabdomeres 1 to 6. It appears that only two photopigments are present in the eyes of flies and, consequently, that their color-vision system, if it exists, is dichromatic.

Dichroic absorption properties

Langer's microspectrophotometric measurements on single rhabdomeres of the *Calliphora* eye (1965) revealed dichroic absorption effects, mainly in the spectral range of from 500 to 520 millimicrons, to linearly polarized light. As the dichroism disappears if the photopigment present in the rhabdomeres is bleached, the oriented arrangement of the chromophores of pigment molecules probably causes the observed effect.

Kirschfeld (1969) succeded in demonstrating dichroic effects directly by microscopic inspection of *Musca* eye preparations. He found that maximal extinction in the different rhabdomeres (at 510 millimicrons for 1 to 6 and at 480 for 7) of an ommatidium takes place at different angular orientations of a linearly polarized light beam. The directions of polarization are, for rhabdomeres 1 to 6, oriented parallel to the axes of their microvilli, whereas, for rhabdomere 7, maximal extinction is found if the vector of polarization is oriented vertically to the microvilli axes. This finding is in accord with Langer's results (1965) for rhabdomeres 1 to 6 in the *Calliphora* eye and also with those obtained with different methods by Giulio (1963) and Eguchi and Waterman (1968).

Moody and Parriss (1961) have tried to explain the dichroic absorption properties of rhabdomeres on the assumption that the chromophores of the pigment molecules are arranged randomly within the microvilli membranes. If this model is adapted, more light is absorbed if the E-vector of the stimulating light is parallel and less if it is oriented perpendicularly to the long axes of the microvilli of the rhabdomeres. This agrees with the findings from rhabdomeres 1 to 6 in Musca. Furthermore, the model leads to a 0.5 ratio of the extinction coefficients for minimal and maximal absorption. Taking into account the experimental data of Burkhardt and Wendler (1960), Kuwabara and Naka (1959), and Scholes (1969), Kirschfeld (1969) determined this ratio for rhabdomeres 1 to 6 as about 0.43, a result that is, at least, not in conflict with the hypothesis suggested by Moody and Parriss (1961). The experimental results also lead to the conclusion that the concentration of photopigments should amount to about 10⁴ molecules per μ^2 of microvillar membrane. A rhabdomere (1 to 6) 200 μ in length therefore contains some 2 \times 10⁸ pigment molecules, which absorb about 65 per cent of unpolarized light at a wavelength of 516 m μ .

Although the Moody-Parriss model is not in conflict with the experimental findings from rhabdomeres 1 to 6 in *Musca*, it fails to explain that extinction in rhabdomere 7 (*Musca*) is maximal if the E-vector of the stimulating light is oriented perpendicularly to the long axes of the microvilli. If it is assumed that dichroism of rhabdomeres is caused by the orientation of chromophores situated in parallel to the microvillar membranes, a higher degree of orientation than that assumed by the Moody-Parriss model should therefore be expected in central rhabdomere 7.

Single-quantum effects

Light impinging on the photopigment molecules in the rhabdomeric structures of the compound eye elicits elementary photochemical reactions. These reactions are the first link in the chain of excitation processes in the receptor cells.We may ask whether a single quantum of light is sufficient, or the coincidence of several quanta is necessary, to trigger these elementary reactions (Reichardt, 1965; Reichardt et al., 1968).

In order to simplify the theoretical considerations, it is assumed here that a number of photopigment molecules, N, of a single rhabdomere are situated in an area F. Every molecule with its molecular cross section, q, takes up the fraction q/F of F. If a light flux, j, of the number of quanta, n, per unit of time impinges on F, the pigment molecules may absorb quanta. If we make the general assumption that it takes z or more quanta per time, τ , to convert an inactive molecule into an activated one, the mean rate, \bar{r} , of photochemical reactions per rhabdomere and flux j is then given by the expression

$$\bar{\mathbf{r}}/\mathbf{j} = N \times \mathbf{q}[\mathbf{j} \times (\mathbf{q} \times \tau/\mathbf{F})]^{\mathbf{z}-1}/\mathbf{z}! \times \mathbf{F}.$$
(1)

In the case of a one-quantum process (z = 1), equation (1) reduces to $\bar{r}/j = (N \times q)/F$. The quantum yield does not depend on the flux, j. The molecular cross section, q, is a constant. In the case of a two-quantum reaction (z = 2), we have $\bar{r}/j = N \times Q/F$, in which $Q = j \times (q \times \tau/2F)$. The quantum yield depends linearly on j, which is to say that the effective molecular cross section, Q, changes proportionally with the quantum flux, j.

The following two light programs were selected (Reichardt, 1965) to test whether the optomotor response depends on a single-quantum or on a multiquantum reaction. Program 1 consisted of a light stimulus, the flux of which was constant in time and equal to j_1 . In program 2, the stimulus consisted of a sequence of short light pulses: duration, Δt ; peak amplitude, j_2 ; pulse frequency, f = 1/T; and average flux, j_1 . The average number of quanta applied per time unit is evidently the same in both programs.

Both programs should evoke the same average rate of photochemical reactions when applied to a one-quantum receptor. If, however, these programs are applied to a multiquantum receptor, program 2 may trigger a higher

photochemical reaction rate than does program 1. The maximum factor by which the average reaction rates may differ is easily derived for the two-quantum case. As j₂ is greater than j_1 by a factor $T/\Delta t$, the effective molecular cross section, Q, is enlarged by this factor. Consequently, under program 2 the two-quantum receptor is $T/\Delta t$ times more efficient than under program 1 and, conversely, the average rate of photochemical reactions is enlarged by the same factor. The effect predicted for the two-quantum receptor depends on the magnitudes of τ , Δt , and T. One expects to find the predicted effect if $\tau < \Delta t$; if, however, $\Delta t < \tau < T$, the individual light pulse is integrated over the time interval, and therefore the expected increase in the average rate of photochemical reactions is smaller than T/ Δt . The increase factor declines to one when $\tau \geq T$, because in this case two or more pulses are integrated in time and, consequently, the effect does not appear. Under these conditions, multiquantum receptors behave as one-quantum receptors do, and do not respond differently to the two different light programs.

It should be pointed out that our considerations are valid only if $j(q/F) \times \tau \ll 1$. This condition contains the requirements for extremely low quantum rates per receptor. Furthermore, the concentrations of the inactive photopigments in light should be essentially the same as those for experiments carried out in darkness. Only under these conditions can one expect that the kinetics of the photochemical reactions depend exclusively on the quantum rates.

The test experiments were carried out with females of *Musca*. The torque exerted by *Musca* during fixed flight was utilized as the quantitative measure of the optomotor reactions of the insect to light programs 1 and 2. A test fly was suspended by a torque compensater at the axis of a rotating cylinder that carried an illuminated periodic pattern of 45° in spatial wavelength. In Figure 4, a typical experimental result is presented.

These results are also typical for a number of experiments carried out with different light-pulse frequencies down to 10^{-1} Hz. The tests were made at a brightness level of 2 × 10^{-2} Apostilb, or about 200 absorbed quanta per second in one of rhabdomeres 1 to 6. As the concentration of pigment molecules per rhabdomere amounts to about 2 × 10⁸ for the quantum rates in question, an individual pigment molecule is hit, on the average, every 10⁶ seconds by a single quantum of light. If we assume that regeneration of the bleached pigment, as measured for rod and cone pigments by Rushton (1964), takes about 100 seconds, only 0.01 per cent of the pigment molecules in a rhabdomere are bleached. Therefore, it is unlikely that changes in the concentrations of the inactive photopigments influenced our experimental results and their interpretations.

The observations summarized in this section accord

FIGURE 4 Test of single-quantum or multiquantum reaction in the eye of Musca. Solid curve: Optomotor reaction versus average brightness (given in Apostilb units; 1 Apostilb = 10^{-4} Lambert) of patterned cylinder. Illumination with light program 1. Spatial wavelength of patterned cylinder, $\lambda = 45^{\circ}$; pattern contrast, m = 21 per cent; angular speed of pattern, $w = 49.25^{\circ}/\text{sec.}$ Response curve represents the averages obtained from five individual flies. These averages and standard errors are not shown in the Figure. Average standard error is ± 0.15 dyne \times cm. Closed circles and open circles: closed circles represent averages obtained from four individual flies with light program 1. The standard error, $\pm \sigma$, of each average, indicated by vertical lines, is calculated from five measurements taken from one individual fly. The open circles near the abscissa value 10⁻² Apostilb represent response averages obtained from the same flies under light program 2. Pairs of closed and open circles at the same abscissa value were obtained from one individual fly. Light program 2 consisted of pulsed light with the same average quantum flux as in program 1. Pulse frequency, 500 c/sec; pulse duration, 1.5×10^{-5} sec; peak intensity of pulse to average intensity, $j_2/j_1 = 133$. Open circles near abscissa value 10° Apostilb demonstrate strengths of optomotor responses to be expected under light program 2 for a two-quantum receptor if condition $\tau \leq 1.5 \times 10^{-5}$ sec is fulfilled. The abscissa values of these open circles are derived from the abscissa values of open circles actually measured and multiplied by the factor $j_2/j_1 = 133$. This factor determines the increase in effectiveness during program 2, because the effective molecular cross section of the two-quantum receptor changes by this factor. Horizontal broken lines indicate these shifts of open circles; vertical broken lines give significant limits for one- versus two-quantum receptors. Spatial wavelength of patterned cylinder, pattern contrast, and pattern speed is the same as described above. (From Reichardt, 1965.)

with the hypothesis that one single quantum of light is sufficient to elicit an elementary photochemical reaction, which, in turn, triggers an elementary photoreceptor response, detectable by the mechanism of movement perception.

Signal-to-noise ratio

In the preceding section, I have shown that optomotor responses of flies can be elicited under low quantum rates. At the absolute response threshold, these rates may be as low as about one quantum absorbed per second and per rhabdomere. The Poisson statistics of the light quanta should therefore result in a significant level of noise in the light signals received by the photoreceptors.

We (Fermi and Reichardt, 1963) investigated the way in which the contrast required of a rotating stimulus pattern depends on the mean brightness, \overline{I} , of the pattern if a justmeasurable response is elicited. A typical result of this dependence is plotted in Figure 5. Below quantum rates of about 200 per second, in one of the rhabdomeres 1 to 6, pattern contrast, m, and mean brightness, \overline{I} , are empirically related by

$$\log m + \frac{1}{2} \log \overline{I} = \text{const. or } m \sim \overline{I}^{-1/2} \,. \tag{2}$$

One can easily calculate that this equation is consistent with the hypothesis that the noise resulting from the statistics of the light quanta absorbed by the photoreceptors is the principal cause of the breakdown of the optomotor response. During a fixed time interval, the mean number,

FIGURE 5 The degree of modulation of a sinusoidally changing light flux received by the receptors of the compound eyes of *Musca* as a function of the mean number, \bar{n} , of absorbed quanta per second, and receptor (1–6) at the optomotor response threshold. Dots represent means of individual measurements, and vertical lines are standard errors of the means. (From Eckert, 1970.)

 \bar{n} , of quanta absorbed by a photoreceptor is proportional to the mean brightness I. The actual number of quanta absorbed will vary randomly in accord with a Poisson distribution with mean n. The fluctuations of n about its mean, n, represent a "quantum noise" that sets a limit to the brightness differences that can be distinguished by the receptor. A measure of the size of these fluctuations is given by the standard deviation of the distribution of n. Because n has a Poisson distribution, its standard deviation is $(\bar{n})^{\frac{1}{2}}$. It follows that if $\Delta \bar{n}$ is the additional mean number of quanta that are absorbed when the brightness is raised from \overline{I} to $\overline{I} + \Delta \overline{I}$, then $\Delta \overline{n}$ must be greater than $(\overline{n})^{\frac{1}{2}}$ if the two brightnesses are distinguishable. Hence, the relationships $\Delta \overline{I} \sim \Delta \overline{n} \sim (n)^{\frac{1}{2}} \sim \overline{I}^{\frac{1}{2}}$ would hold at the threshold of brightness discrimination. This relation is equivalent to $\Delta ar{I}/I \sim m \sim ar{I}^{-\frac{1}{2}}$, which represents the measured dependence of threshold contrast on background brightness.

The measured relationship is different from that which would be expected if the threshold were determined by the thermal noise in the photoreceptors, the neuronal noise in the nervous system, or both. If the breakdown of the reaction were determined by these "internal" noises, the signalto-noise ratio should have a constant, critical value at the threshold of the reaction. The amplitude of the internal noise would, at low quantum rates, not be expected to depend on the light signals received by the photoreceptors, so the value of the signal-to-internal-noise ratio should depend only on the signal amplitude. The amplitude of the light signal received by each photoreceptor is proportional to the product $m\bar{I}$ of the contrast and mean brightness of the rotating stimulus pattern. Hence, the relationship $m\bar{I} =$ const. or, equivalently,

$$\log m + \log \bar{I} = \text{const.} \tag{3}$$

should hold at the threshold of the reaction. It may be seen in Figure 5 that this relationship would represent a poor fit to the measured dependence of threshold contrast on mean pattern brightness at very low quantum rates.

These considerations therefore indicate that internal noise obviously does not represent a principal factor determining the threshold of the optomotor response.

The representation of the optical environment in the nerve–cell layer of the first optical ganglion

I have pointed out that the projection of the optical environment onto the retina is determined by the structure and by the geometry of the compound eye, as well as by the properties of the dioptric system. Light from a point source mounted in the optical environment is received by seven (eight) different rhabdomeres in adjoining ommatidia. The correspondence between individual points in the optical environment and the individual receptors of the retina is, therefore, a one-to-seven and not a one-to-one relationship.

The projection from the retina on the first optical ganglion lamina merely depends on the nerve-fiber connections between these two levels (Vigier, 1907, 1908, 1909; Trujillo-Cenóz, 1965; Trujillo-Cenóz and Melamed, 1966; Braitenberg, 1967; Strausfeld, 1970a). The fibers leading from the sensory cells of individual ommatidia twist 180° and distribute themselves at the level of the lamina, which has a periodic structure of elements called optic cartridges (Ramón y Cajal and Sanchez, 1915) or neurommatidia (Villianes, 1892), arranged in a hexagonal array. The total number of cartridges matches that of the ommatidia. Every cartridge does not have two interneurons associated with it, as was once thought. Rather, it has four (Braitenberg and Strausfeld, 1970; Strausfeld, in preparation) and receives fibers from a group of six adjoining ommatidia—those that contain the six retinular cells of the group that collects optical information from one point of the environment only. Consequently, the projection between the retina and the lamina is based on a six-to-one, and not on a one-to-one, correspondence between retinular cells and cartridges. Hence, the representation of the optical environment in the nerve-cell layer of the lamina is such that an individual point of the environment is represented in an individual cartridge. Cells 7 and 8 in each ommatidium (the long visual fibers) project as pairs (Strausfeld and Blest, 1970) through the lamina and terminate in the medulla, after crossing the first optic chiasm.

Figure 6A and B are drawings from Strausfeld of the laminar region. Detailed explanations of these drawings are given in the figure captions. Most important in this connection are the findings of Braitenberg (1969), Strausfeld (1970b), and Braitenberg and Strausfeld (1970), who claim that there are at least two, and possibly four, types of lateral connections present in the lamina. Collaterals (Figure 6A) from one of the cartridge neurons (L4) extend vertically to two adjacent cartridges, where they possibly make synaptic contacts. Tangential fibers (Figure 6B), originating from cell bodies beneath the lamina, spread laterally over an area of about three to four cartridges in both vertical and horizontal planes. Information from these areas could be relayed together by single collaterals to the medulla (Strausfeld, 1970a).

An important consequence of these results derived from *Musca*, as well as other species of Diptera, is that an individual cartridge does not receive information from two distinct positions of the environment via receptor elements, a necessary condition for any mechanism that must perceive movements by the correlation of data. Nevertheless, the cartridges can no longer be excluded as the possible sites for movement detection, because lateral interconnections are present between neighboring cartridges. Further electrophysiological and behavioral work seems necessary before the functional roles of the synaptic links between neighboring cartridge interneurons can be explained fully.

At this point we may come back to the surprising finding I reported earlier in this chapter—that internal noise does not influence the threshold of the optomotor response. This result is understandable for the receptors, because their activation energies are about a factor 80 above the kT level, but it is not easy to conceive that the neuronal pathways for the next synaptic stages involved in the information transfer -as, for instance, the lamina-operate at the theoretical limit, particularly because nerve spikes, as information carriers, have not yet been recorded either from the receptor cells or from the laminar region. The question arises whether there are coincidence-anticoincidence devices present in the circuitry of the laminar region that may be responsible for a drastic increase in signal-to-noise ratio. The structural complexity of the lamina and its connection with the second synaptic region (the medulla) does not rule out such a possibility, but at present only a highly speculative statement could be put forward to support the suggestion.

Evidence for representation from electrophysiological data

I have reported that nervous responses should be evoked in the "output" of a laminar cartridge by light from a single point in the environment, received by the associated group of six ommatidia.

Scholes (1969) succeeded in recording graded potentials to short flashes of light, provided by a point source, from a laminar component in the upper frontal quadrant of the eye of Musca. The time course of these graded laminar responses turned out to be very similar to those he recorded from retinular cells 1 to 6. The responses were also found when light rays were directed on a single ommatidium, rather than on the whole eye. This was achieved by shielding the corneal surface with a mask that contained a hole 10 to 15 μ in diameter. The mask was moved over the corneal surface, some 75–100 μ distant from it, and contour lines were drawn round the points on the corneal surface at which light was equally effective in eliciting a cartridge response. The result of the experiment, shown in Figure 7, shows that the contours correspond convincingly to the pattern of ommatidia that project onto the single cartridge. Sensitivity to illumination of rhabdomeres 7 and 8 is very low, a finding that accords with the histological observation that the long visual fibers pass the lamina without making synaptic contacts with monopolar interneurons.

Scholes (1969) was also able to show that the graded responses found at the laminar output to light stimulating the whole eye are the sum of the partial responses from the six individual receptors that contribute to the laminar response. This result was to be expected, as the optomotor responses to pulsed light (see section on Single-Quantum Effects, above) did not reveal any coincidence of signals either at the receptor level or at those stages peripheral to the process of perception.

It should also be mentioned that angular sensitivity distributions, measured at laminar outputs, amounted to about the same half-width as in distributions measured from retinular cells. This result suggests that the optical axes of the associated group of six rhabdomeres are nicely aligned in parallel.

Movement perception

The localization of the movement-perception system in the insect optical ganglia, the central brain, or both, is still an unsolved problem. An analysis of the system, carried out on the beetle *Chlorophanus* and the flies *Drosophila* and *Musca*, was originally based on input and output response relations (Hassenstein, 1951; Reichardt, 1957; Hassenstein, 1958; Reichardt and Varjú, 1959; Varjú, 1959; Reichardt, 1961; Götz, 1964; McCann and McGinitie, 1965; Varjú and Reichardt, 1967). More recently, electrophysiological investigations have been undertaken with the aim of localizing the movement perception system in the higher optical ganglia (McCann et al., 1966; Bishop and Keehn, 1967; Bishop et al., 1968).

Behavioral studies have led to the formulation of a mathematical model by means of which responses to given pattern stimuli can be predicted (Reichardt, 1957, 1961). An essential feature of the model is that it must take into account only the transformations of signals from adjacent sensory inputs and their interactions during the process of perception. This is because the strength of the optomotor response elicited by the stimulation of the compound eyes is the sum of all the partial responses evoked by the interactions of data from neighboring sensory inputs. This finding can be expressed by saying that, with respect to movement perception, the compound eye is isotropic in function.

The model of movement perception envisages two crossconnected information input channels (A and B) and a common output channel to the motor system (see Reichardt, 1961). The inputs A and B represent two adjacent cartridge outputs, fiber terminals, or both, that lead from sensory cells 7 and 8; A and B obviously act as input elements that provide the minimum detector requirement for the optomotor response. The two inputs transform the space and time coordinates of the stimulus into the time functions L_A and L_B . The time functions can be considered to be sums of an average light flux, C, and of a fluctuating light flux, G(t), the average value of which is zero. That is

$$L_{A} = C + G(t), L_{B} = C + G(t - \Delta t),$$
 (4)

FIGURE 6. A. Centripetal interneurons of optic cartridges (ending in the second synaptic region, the medulla). I. Crosssections of an optic cartridge at six levels (a to f) through the lamina. Open circles represent receptor elements. Closed circles represent interneuron axis fibers. Retinular-cell endings (1-6) form a crown around two axial monopolar cells (L1 and L2). Long visual fibers (7 and 8) remain outside the crown. The midget monopolar cell (L3) lies within the crown at level b. Sometimes two side branches can be seen at levels b and e, pointing back toward the crown. The tripartite cell (L4) runs parallel to L3. II. Reduced silver stains show the outline of the relative positions of L1, L2, L3 and L4 of each optic cartridge. III. Silhouettes of monopolar cells as seen in Golgi preparations. L2 has two distinct sets of processes, one of which, at levels a and b, could extend as far as the processes of L2 in the two cartridges adjacent to it. However, their synaptic relationships are, as yet, unknown. The processes of L2 deeper in the lamina at levels c, d, and e are arranged radially from the axis fiber

and extend between the retinular cells of a crown (Strausfeld, 1970b). L1 has a single set of processes, also disposed radially from the axis fiber, which are restricted to within the crown of retinular-cell endings. Characteristically, L3 has a kinked appearance and usually has two tiny unilateral side branches. L4, like L3, is invariably situated posterior to the crown of the retinular cell. It has one or two side branches at level b, and three branches at level f. The shortest of these extends into the adjacent crown, anteriorly. The other two extend dorsally and ventrally in a characteristic pattern, as shown in IV. L1-L4, in III, shows a reconstruction of the geometrical relationships between the four monopolar cells. L2 has been partly cut away to reveal the narrower spread of L1. IV. A schematic drawing, derived from reduced silver preparations, showing a portion of the lamina, cut tangentially, at level f. The exceedingly regular network of the L4 side branches could provide lateral interaction between triplets of optic cartridges.

502 NEURAL SUBSYSTEMS AND PHYSIOLOGICAL OPERATIONS

B. The periodic arrangements of elements in the lamina. Abbreviations: R, retinular cell ending; LV, long visual fibers (7 and 8 in Figure 6AI); F, fenestration layer of the lamina (in which retinular cell decussation is localized); P, external plexiform layer (synaptic layer) of the lamina; 10C, the outer 15-20 m μ of the first optic chiasma. I. Crowns of retinular cells (indicated in horizontal section) are repetitively arranged in the lamina, as are the pairs of long visual fibers that project through the lamina and end, finally, in the medulla. II. The repetitive arrangement of four monopolar cells (L1-L4). Tangential processes (T) are regularly arranged, with respect to cartridges, there being a system of ascendent branches spaced one to about every five cartridges. Subsequent processes invest the outer face of the plexiform layer and invade it between crowns of the retinular cell. These tangentials have connections to the medulla (Strausfeld, 1970a) and could possibly relay information from groups of cartridges to the second synaptic region, as well as provide an anatomical basis for intercartridge interaction in the lamina. III. The repetitive arrangement of morphologically "centrifugal" endings derived from elements in the medulla. Of the three forms, one (be) invests the outside of a crown of retinular-cell endings and the other two (c) are situated between the long, visual-fiber pair and the L3 and L4 pair outside the crown. All three types cross over the first optic chiasma parallel to the fibers of centripetal elements from the lamina to the medulla. Lateral interaction could also be mediated by amacrine cells (Ramón y Cajal and Sanchez, 1915), which may have a periodic arrangement in the lamina. They are not included in this diagram. (Diagrams are from Strausfeld, 1970a, and Strausfeld, in preparation. The orientation of elements in AI is from Braitenberg, 1970.)

50 µ

FIGURE 7 A contour map showing the distribution of sensitivity over the surface of the cornea in the lamina of a *Musca* compound eye. The sampling points, each of which was tested two to four times during the experiment, are indicated by the intersections of the bars in the margins. The dimensions of the facets in the eye regions concerned, measured after the experiments, are sketched behind the contour lines. The experiment was made on the upper frontal quadrant. (From Scholes, 1969.)

in which t is the time and Δt the time interval between the reception of a stimulus by A and its reception by B.

The model envisages further that the time functions L_A and L_B are transformed by a succession of directly connected and cross-connected components that carry out linear transformations (filters D, F, and H), multiplication, and time averaging.

The strength of the response, R, predicted by the model, to a moving contrasted pattern is given by the expression

$$R = \int_{0}^{+\infty} W_{DF}(\eta) \int_{0}^{+\infty} W_{DH}(\xi) \Phi_{GG}(\eta - \xi - \Delta t) d\xi d\eta$$

$$= \int_{0}^{+\infty} \int_{0}^{+\infty} W_{DH}(\eta) \int_{0}^{+\infty} W_{DF}(\xi) \Phi_{GG}(\eta - \xi - \Delta t) d\xi d\eta , \quad (5)$$

in which W_{DF} and W_{DH} describe the transformations in the directly connected and cross-connected channels in terms of filter-weighting functions.

$$\Phi_{GG}(\eta - \xi - \Delta t) = \frac{1}{2T} \int_{-T}^{+T} G(t - \eta) G(t - \xi - \Delta t) dt$$
$$\lim_{T \to \infty} T \to \infty$$
(6)

designates the autocorrelation function of the light flux fluctuation G(t) and η and ξ integration variables.

The response, R, depends on two parameters of the stimulus: the speed w $\sim 1/\Delta t$ and the structure of the moving pattern, which determines the autocorrelation function Φ_{GG} . The special character of the response also depends on the transformations of the components D, F, and H, which reflect functional properties of the movement-perception system.

Most important in this connection is the dependence of R on Φ_{GG} and not on G(t) itself. If G(t) is decomposed into Fourier components, any changes in the phase relations of these components do not influence R, as they belong to the class of transformations to which Φ_{GG} and, consequently, R, are invariant. This prediction of the theory was tested experimentally and confirmed.

We may conclude from these considerations that in the process of movement perception, as in any perceptual process, sensory information is destroyed—in the present case, in order to abstract motion from the displacement of individual points in the optical surround relative to the eye of the insect.

Determination of resolution and contrast transmission

The fundamental optical properties of the fly's compound eyes, expressed by $\Delta \varphi$ and $\Delta \rho$, can be determined by optomotor response measurements. Before turning to the experimental results, we shall derive from equation (5), which describes the input-output relations of the model for movement perception, how the strength of reaction R depends on the parameters $\Delta \varphi$ and $\Delta \rho$ under elementary stimulus conditions. Such conditions are realized by a test pattern, the contrast of which changes sinusoidally. If one designates λ the spatial angular wavelength of the pattern, m the contrast (expressed by the degree of modulation), and w the angular velocity of the pattern, it can be calculated from equation (5) that R is given by the expression

$$R \sim m^2 \times f\left(\frac{w}{\lambda}\right) \times \sin\left(\frac{2\pi \times \Delta\varphi}{\lambda}\right).$$
 (7)

Apparently R depends on three terms: (1) the square of the pattern contrast m; (2) the function $f(w/\lambda)$, which reflects transfer properties, and (3) the so-called interference term $\sin(2\pi \times \Delta \varphi/\lambda)$, which contains λ and $\Delta \varphi$, but not w.

So far we have established only the predicted dependence of R on $\Delta \varphi$, under the special stimulus conditions selected here, but not yet the dependence on $\Delta \rho$. The reason is that, in setting up the mathematical model for movement perception, we have tacitly assumed that the model inputs A and B receive their information from only two distinct points in the optical surround but not from areas of finite size. On this mathematical assumption, the pattern contrast, even for extremely small spatial wavelengths (λ), is transmitted to A and B without loss. In reality, however, such is not the case, as the size of the visual fields of the receptors is finite. Consequently, for decreasing spatial wavelengths of the stimulating pattern, the contrast received by the rhabdomeres is diminishing. As has been stated before, no distinct boundaries of these visual fields exist, but a region within the light sensitivity decreases continuously, somewhat in accordance with a Gaussian distribution function with half-width $\Delta \rho$.

When a Gaussian-like, visual-field distribution is taken into account, and m_1 is designated as the contrast of the sinusoidal pattern and m_2 as the contrast transmitted to the receptor level (Fermi and Reichardt, 1963; Götz, 1964, 1965), m_1 and m_2 are related by the expression

$$\mathbf{m}_2 = \mathbf{m}_1 \times \mathbf{h}(\lambda; \Delta \rho) , \qquad (8)$$

with the contrast transfer function h (λ ; $\Delta \rho$) = exp [$-(\pi^2/4\ln 2) \times (\Delta \rho/\lambda)^2$] and $\Delta \rho \ll \pi$. Replacing m in equation (7) by m₂ from equation (8), for the strength of reaction R under the given stimulus conditions, we arrive at the expression

$$R \sim m_1^2 \times h^2(\lambda; \Delta \rho) \times f\left(\frac{w}{\lambda}\right) \times \sin\left(\frac{2\pi \times \Delta \rho}{\lambda}\right),$$
 (9)

which consequently depends on both parameters $\Delta \varphi$ and $\Delta \rho$.

Experiments on Drosophila and Musca, carried out with sinusoidally changing contrast patterns, have shown that, if λ is kept constant but w—and, therefore, also w/ λ —are changed, the response R throughout the whole range of w does not change sign. Consequently, $f(w/\lambda)$ does not change sign under a variation of w/ λ . From equation (9) it follows that the sign and, therefore, the direction of the optomotor response, depend exclusively on the interference term

$\sin (2\pi \times \Delta \varphi / \lambda)$.

Within the wavelength region $2\Delta\varphi \leq \lambda < +\infty$, the moving sinusoidal pattern is resolved, as the number of samples received per period λ at any time is greater than or equals two. If, however, λ enters the region $0 < \lambda < 2\Delta\varphi$, optical resolution of the periodic pattern breaks down, because fewer than two samples per wavelength are received under this condition, and, as a result, the information content of the pattern is transmitted incompletely. The resolution limit of the model with $\Delta\varphi$ spacing between the adjacent inputs is therefore determined by $\lambda = 2\Delta\varphi$, the first zero crossing of the interference term $\sin(2\pi \times \Delta\varphi/\lambda)$.

These theoretical considerations constitute the necessary background for our understanding experimental results from *Drosophila* (Götz, 1964, 1965) and *Musca* (Eckert, 1970) undertaken with the aim of determining the parameters $\Delta \varphi$ and $\Delta \rho$.

The strength of optomotor reaction was measured as a function of λ , whereas w/λ and consequently $f(w/\lambda)$ were kept constant. In these experiments, the contrast of the sinusoidal patterns amounted to $m_1 = 1$. The first zero crossing of the response was found for $\lambda_0 = 9.2^\circ$ in *Drosophila* and for λ_0 = 4.0° in *Musca*. From these results one derives an average divergence angle of $\overline{\Delta \varphi} = 4.6^\circ$ in *Drosophila* and $\overline{\Delta \varphi} = 2.0^\circ$ in *Musca*. The angles coincide with values measured between the axes of adjacent ommatidia in horizontal cross sections of eye preparations (Braitenberg, 1967).

As an important consequence of these behavioral tests, we can now state that optical resolution is determined by the divergence angle between the optical axes of adjacent ommatidia, and not by the smaller angles between the optical axes of neighboring rhabdomeres. This result is in full agreement with the established one-to-seven correspondence between an individual point in the optical environment and its representation in seven different rhabdomeres in seven different ommatidia.

If patterns with spatial wave lengths, λ , below the optical resolution limit are applied, the strength of the optomotor

reaction decreases, which is the result of the increasing contrast reduction by the sensitivity distributions, $h(\lambda; \Delta\rho)$, of the receptors. From a pair of experiments, in which $f(w/\lambda)$ was kept constant but λ and m_1 were varied, the values of $\overline{\Delta\rho}$ were determined. It turned out that $\overline{\Delta\rho}$ is about 3.5° for *Drosophila* and 1.7° for *Musca*.

The determination of the two parameters $\Delta \varphi$ and $\Delta \rho$ lead to the question of whether their values are related to each other in such a way that they form an optimal pair. That is to say, the optical resolution limit of the eye is, as we have seen, determined by the divergence angle $\Delta \varphi$ between the optical axes of adjacent ommatidia. The smaller $\Delta \varphi$ is, the better the resolution and, therefore, the finer the details of the optical surround that can be resolved by the eye. A corresponding statement holds for $\Delta \rho$. The smaller $\Delta \rho$ is, the better the contrast transmission from the optical surround to the receptor and the cartridge layer of the eye. From a purely theoretical point of view, the best resolution and contrast transfer could be reached if $(\Delta \varphi; \Delta \rho) \rightarrow 0$ and, consequently, the number of ommatidia per eye equals $N \rightarrow$ $+\infty$. If these limits are approached, the light flux Φ into an individual ommatidium or a receptor would also approach zero as $\Phi \sim (\Delta \varphi \times \Delta \rho)^2$. Therefore, the signal-toquantum noise ratio would reach intolerable values and the optical information received by the receptors of the eye would be destroyed, so that the advantages of perfect resolution and contrast transfer would be lost. Hence, the product $\Delta \varphi \times \Delta \rho$ must exceed a certain limit, a condition that does not determine the numerical value of the ratio $\Delta \rho / \Delta \varphi$. Again, from a theoretical point of view, it can be seen easily that, for a fixed value of the product $\Delta \varphi \times \Delta \rho$, there must exist a ratio $\Delta \rho / \Delta \varphi$, which leads to an optimal combination of both resolution and contrast transfer. For the sake of argument, let us assume that $\Delta \varphi$ is large and consequently $\Delta \rho$ is small. Under these conditions, contrast transfer would markedly exceed the limit of optical resolution. If, on the other hand, $\Delta \varphi$ is small and $\Delta \rho$ is large, optical resolution could not be utilized to its limit, as contrast transfer at this limit would be very poor. A mathematical treatment of this problem by Götz (1965) has led to the result that under the condition $\Delta \varphi \times \Delta \rho = \text{const.}$, optimal resolution and contrast transfer are established if $\Delta \rho / \Delta \varphi$ = 0.88. The experimental values derived from Drosophila and Musca are 0.76 and 0.85. The value of the optical parameters $\Delta \varphi$ and $\Delta \rho$ of the compound eyes of Drosophila and Musca therefore nearly meet the requirements for optimal resolution and contrast transmission.

Visual detection and fixation of objects

In the past, the analysis of movement perception in insects has been carried out by measuring the torque response of fixed flying insects to the movements of patterns. In these experiments, the pattern velocities relative to the test fly were always determined and kept under control by the experimenter ("open loop" conditions).

Investigations of the behavior of flies (*Musca*) were recently undertaken by Reichardt and Wenking (1969) with the aim of analyzing the processes of visual detection and fixation of objects. For this purpose, a servo-system was developed that enables a test fly to operate under "closed-loop" conditions; that is to say, a fly controls the angular velocity of its surround by its own torque response. The principal components of the mechano-electronic device are given in Figure 8. If an object (a single, black, vertically oriented stripe) is mounted on the inner surface of the cylinder, no significant indication of any reaction by the fly to the object, irrespective of its angular position, is found in the average torque response under open-loop conditions. If, however, the servo-system driving the cylinder is coupled to the torque response (closed-loop condition) of the fly, the object is moved into the direction of flight, where it reaches a stable fixation position.

In Figure 9, a typical experimental result is presented, giving the probability of object positioning versus the angular position of the object during the phase of object fixation for different coupling-in conditions. At present,

FIGURE 8 Mechano-electronical device for the quantitative study of detection, fixation, and discrimination of visual objects. The essential components of the device consist of a torque compensator with linear response characteristics and a cut-off frequency near 1 kHz; a servomotor with a driving shaft that carries a patterned ground-glass cylinder and a ring potentiometer that signals the angular position of the patterned cylinder; an electronic device that controls the motor speed and direction by the torque signal of the fixed flying test fly suspended from the torque compensator. The cut-off frequency of the control device is limited to 50 Hz. The instrument can be used in two different modes of operation: 1. Free running mode. A constant torque signal generates a constant angular *velocity* of the patterned cylinder. The direction of rotation is determined by the direction of the torque. 2. Stabilized mode. The pattern center is elastically stabilized at a selected angular position, φ . In this mode, a constant torque signal generates a constant angular *displacement* of the patterned cylinder. The direction of the displacement is determined by the direction of the torque.

Abbreviations: Dig. V., digital voltmeter; DSC, discriminator; G, generator; J, integrator; M, signal multiplier; MT, magnetic-tape recorder; OA1–OA8, operational amplifiers; SDM, signal demodulator; TS, time switch.

FIGURE 9 Experimental results obtained from the instrument and described as mode 1 in legend of Figure 8. The object consists of a single, black, vertically oriented, stripe 6° in width. The Figure gives the probability of object positioning versus the angular position of the object during the phase of object fixation for different coupling-in conditions, KF. Calibration: 1 dyn \times cm torque signal generates 3.4 revolutions per second of the patterned cylinder for KF = 2/10. Fixation of object is very pronounced for KF = 4/50 and less pronounced under the condition of stronger coupling, KF = 8/50. Direction of flight: 0 degree. (Fly was fixated and pointed in a direction for which the angular coordinate was set at zero.) The data for an individual distribution were taken during a time interval of 180 seconds. Number of data per distribution is about 6000.

the correct simulation of the natural coupling-in conditions is not known; consequently it is an open question whether the instability during fixation at high coupling-in values is introduced by the fly, by the motor drive system, or by both.

In another sequence of experiments, presented in Figure 10, the angular width of the black stripe was varied. When the stripe is as much as about 40° in angular width, the flies fixate at its center; between 60° and 320° they fixate at a portion of the stripe near the edges. When a 350° black stripe is presented, the fly is confronted with the reversed-contrast condition with respect to the 10° stripe experiment shown in the Figure. That is to say, a black-on-white pattern is replaced by a white-on-black pattern, both 10° in angular width. Whereas the black-on-white pattern is clearly fixated, the white-on-black pattern essentially is not, which follows from the nearly flat probability distribution in Figure 10.

FIGURE 10 Experimental results from mode-1 operation, with single, black, vertically oriented stripes of different angular widths (10°, 40°, 90°, 180°, 270°, 320°, and 350°). Coupling-in condition is kept constant and amounts to KF = 3/50. The probability of object positioning is plotted versus the angular position of the object during the phase of object fixation. For stripe widths up to 40°, the test fly fixates the center of the stripe. For increasing stripe widths, up to 320°, the test fly fixates a portion of the object near one of the two edges. At a stripe width of 350° fixation disappears. Data for an individual distribution were taken during 180 seconds.

The experimental findings reported so far suggest that the resulting movement of the object, during the phase of object transfer into the fixation position, results from an

TRANSDUCTION AND PROCESSING OF OPTICAL DATA 507

asymmetry in the strength of the response of the fly to progressive and regressive motions of the object relative to its compound eyes. This suggestion was tested and confirmed with the aid of an additional feedback loop inserted into the control device (see Figure 8), by means of which the object is elastically stabilized at a selected angular position. If, under these conditions, the torque response of the test fly is coupled to the cylinder-control device (closedloop condition), the fly generates a probability distribution of object positioning, the maximum of which is displaced to an angular position situated between the direction of flight and the stabilized open-loop position.

Figure 11 shows that the angular displacement, which is

strongest in the frontal part of the two compound eyes, reflects the asymmetry of the response and indicates, for every position, the resulting average torque response that is responsible for the observed phenomenon of object transfer in the direction of flight. The upper distribution in Figure 11 represents a control experiment of the same test fly under normal (nonstabilized) fixation conditions.

The method described seems to be appropriate and will be applied, in both modes of operations, to the analysis of pattern discrimination by insects.

Summary

During the past years, the visual system of insects, particularly of flies, has been used increasingly as a model for an analysis of uptake, transduction, and processing of data in the central nervous system. The total number of neurons in the eye of a fly is about 5×10^5 . These neurons are composed of definable classes of elements that are replicated many times in an orderly way. Electrophysiological microprobing of the retina and the ganglia is possible and has been applied with the aim of tracing the information flux at different levels. Flies possess a rich repertoire of behavior. *Drosophila*, especially, has been investigated genetically in great detail.

The account I present here concerns the application of three methods—histological, behavioral, and electro-physiological—to the analysis of structure and function of the optical system of flies (*Drosophila* and *Musca*).

The discussion of the optical properties summarizes the way in which the optical environment is represented in the photoreceptor layer of the compound eye. An individual point in the optical surround is imaged onto seven different receptor structures (rhabdomeres) in seven different ommatidia. Therefore, the correspondence between individual

FIGURE 11 Experimental results from mode-1 and mode-2 operations (see Figure 8). The object consists of a single black, vertically oriented stripe 6° in angular width. The coupling-in condition throughout the various experiments amounts to KF = 6/50. The probability of object positioning is plotted versus the angular position of the object during the phase of object fixation. The upper distribution was recorded in mode-1 operation (Figure 8). The other distributions were recorded in mode-2 operation. The object was here elastically stabilized at the following angular positions: $\pm 45^{\circ}$, $\pm 70^{\circ}$, $\pm 90^{\circ}$, and $\pm 135^{\circ}$. Calibration: KF = 6/50 in connection with an elastic stabilization of strength P = 4 results in a 12° angular displacement of the object for 1 dyn \times cm torque signal. Each distribution generated by the test fly was recorded during 180 seconds. The distributions are shifted toward the direction of flight. The shift is most pronounced at $\pm 45^{\circ}$ and decreases with the increase in angular position of the stabilized object.

508 NEURAL SUBSYSTEMS AND PHYSIOLOGICAL OPERATIONS

points in the surround and the receptor mosaic is one to seven, and not one to one. Consequently, the limit of optical resolution of a compound eye is by a factor seven below the limit one would expect from the spatial separation of rhabdomeres.

Two parameters determine the optical properties of a compound eye: (1) the divergence angle, $\Delta \varphi$, between the optical axes of adjacent ommatidia which sets the limit of optical resolution; and (2) the angular sensitivity distributions of individual rhabdomeres, expressed by $\Delta \rho$, the halfwidth of the distribution. These distributions determine contrast transmission from the optical environment onto the receptor layer. Their quantitative values have been determined and are reported in the section on Determination of Resolution and Contrast Transmission. The product $\Delta \varphi \times \Delta \rho$ determines the quantum flux into an individual rhabdomere, whereas the degree of adjustment between optical resolution and contrast transfer is expressed by the ratio $\Delta \rho / \Delta \varphi$. Also in the section mentioned, it is shown that $\Delta \rho$ and $\Delta \varphi$ form an optimal pair, that is to say, optical resolution meets the requirements of optical contrast transfer.

Two different spectral sensitivities of rhabdomeres are described. It seems that only two photopigments are present in the eyes of flies. The arrangement of the chromophores of the pigment molecules, situated in the rhabdomeres, is such that a strong dichroic absorption effect is observed.

I emphasize the problem of whether an elementary photochemical reaction in the photopigments can be elicited by a single quantum of light or whether this process requires the coincidence of absorption of two or more quanta. The evidence is based on quantitative behavioral data, which accord with the hypothesis that a single quantum of light is sufficient to elicit an elementary photochemical reaction. The reaction, in turn, triggers an elementary photoreceptor response.

If weak optomotor responses are elicited in flies, with very dim illumination, pattern contrast must be set at a high level. Behavioral experiments show that the optomotor response threshold is invariant under a change of pattern contrast, m, and average pattern brightness, \tilde{I} , if the product mI[‡] is kept constant. This finding suggests that the breakdown of the response is caused by the fluctuation of quanta (quantum noise) and not by an internal noise.

I devote the section entitled Movement Perception to summaries of former experiments that led to the formulation of a mathematical theory of the optomotor response. The theory states that, in the formation of movement perception, optical data are processed in the central nervous system in accordance with a first-order correlation process. The important consequence of this finding is that 50 per cent of the information present in the optical environment is selectively destroyed in the process of movement perception. During the last few years, considerable anatomical and

histological work has been done in an attempt to localize correlation processes in the structures of the optical ganglia. These investigations have not been successful so far, but it has been shown that the synaptic junctions that connect the fibers leading from the sensory cells in the retina with the interneurons of the first optical ganglion (lamina) are not responsible for correlating optical data. The evidence is discussed in the sections preceding the one on Movement Perception. The interneurons of the lamina are lumped together in identical groups (cartridges), equal in number to those of the ommatidia. Each group receives synaptic inputs from sensory fibers, which in turn collect optical information from a single point in the optical environment. This finding rules out the possibility of correlating data from two distinct points of the optical environment, a necessary condition for the perception of motion.

Recently, optomotor-response investigations have been extended toward a quantitative analysis of visual detection, fixation, and discrimination of patterns. Some of these experiments are reported. Under fixed flight conditions, flies respond only if an object or pattern is moved relative to its eyes. Progressive motion of an object (progressive with respect to one of the two eyes) results in an optomotor response stronger than regressive motion. This asymmetry of the response is the cause for pattern fixation in the overlap region of the visual fields of the two compound eyes. The center of a vertically oriented black stripe on a white background is fixated if the angular width of the stripe is no greater than about 40°. For a stripe wider than 40°, the test flies fixate portions of the black stripe near the edges. Fixation seems to be limited to black stripes. A white stripe on a black background is not fixated if the stripe width is less than about 10°. The experimental results reported so far suggest that flies possess a nervous mechanism for pattern discrimination.

46 Olfactory Receptors for the Sexual Attractant (Bombykol) of the Silk Moth

DIETRICH SCHNEIDER

Chemoreception and olfaction

RESPONSES to environmental influences or stimuli are fundamental phenomena of living matter. Because organisms are complex chemical systems, it is obvious that chemical stimulus-response functions are found on all levels of organization, from the microbes to the highest metazoans such as insects and vertebrates. In the latter groups we find well-defined chemoreceptor systems: olfaction and taste (Schneider, 1969). These two are distinct modalities; one finds anatomically different input channels responding to certain groups of (adequate) chemical stimuli.

Olfactory organs are highly developed detector systems which respond with short latencies to small numbers of stimulating molecules. They also analyze gas mixtures quite efficiently, as we know from our sense of smell. Our present problem is the detection of one, and not the discrimination of many, different odorous molecules. I describe a specialized odor receptor which transforms a chemical signal of great biological importance into a nervous message. It is necessary to analyze the catching and transport of the odor molecules in the outer structures of the receptor and, subsequently, to look for ways to approach the transducer function, which is the transformation of the stimulus into the bioelectrical response. Finally, I discuss the possible fate of the signal molecule after it has delivered its message, and of other such molecules which did not reach their destination but were adsorbed on inexcitable structures of the animal.

In our laboratory we have studied intensively the activity of insect olfactory receptors in general and sexual attractantreceptor responses in particular, because insects offer a number of opportunities for the experimental approach to olfaction:

- 1. The receptor system is situated on an accessible extremity, the antenna.
- 2. The primary sensory (receptor) cells belong to the epidermal cell layer and, with their dendrites, are in intimate contact with specialized cuticle differentiations.
- 3. All the individual receptor-cell axons run directly to the deutocerebrum without axon fusion. Receptor interaction by collaterals and synapses, or by ephapses, is unknown (Steinbrecht, 1969a).
- 4. Insects not only are able to differentiate among many odors (as do vertebrates), but they also have large numbers of highly specialized receptors for biologically important odors (unknown in vertebrates).
- 5. Odor receptors for such key substances (as, for instance, the excretory messenger substances, or pheromones) are maximally sensitive and may comprise as much as 50 per cent of the olfactory cells of the animal.
- 6. The chemical structure of some pheromones has been analyzed, which facilitates the quantitative physiological analysis.
- 7. Electrophysiological recordings can be made with single

DIETRICH SCHNEIDER Max-Planck-Institut für Verhaltensphysiologie, Seewiesen, Germany

receptor cells and whole sets of receptor organs (antennae).

8. Receptor responses can be compared with the behavior of the animal.

The attractant and the response of the antennal receptors

The striking lure effect of female moths on their mates was known to biologists of the nineteenth century (see Schneider, 1957). At the turn of the century, it was found that the female's lure emanates only from the abdominal epidermal lure glands, but the functional principle of the attraction phenomenon was doubted by some workers in the field. The main reason for these doubts was that none of the glandular products had been isolated and, consequently, had not been tested as a potential olfactory stimulus. Furthermore, the luring stimulus seemed, in some cases, to carry for such long distances that it could not be explained by an odorous message transfer. Last, but not least, the situation was and still is complicated for the experimenter because most of the sexual attractants that have thus far been identified are not odorous to human beings.

The first successful isolation of a sexual-lure pheromone of a moth was accomplished by Butenandt and his coworkers (1959). These investigators chose the domesticated silk moth, *Bombyx mori*, as their experimental animal, because large numbers of glands are available and bioassays are comparatively easy. After many years of chemical work it was found that the lure principle of the female silk moth is an alcohol, which was named "bombykol" (Butenandt et al., 1959):

$$CH_3 - (CH_2)_2 - \overset{H}{C} = \overset{H}{C} - \underset{H}{C} = \overset{H}{C} - (CH_2)_8 - CH_2OH_3$$

Hexadeca-10-trans, 12-cis-dien-1-ol = bombykol

This substance, as well as its geometrical isomers, was subsequently synthesized and became a useful tool for the physiologist (Butenandt and Hecker, 1961; Butenandt et al., 1962; Hecker, 1960). Recently bombykol has again been synthesized and labeled with tritium (Kasang, 1968). Since the early 1950s we have been working with the Bombyx lure system, using behavioral, electrophysiological, and histological techniques. Because the subject has previously been reviewed (Schneider, 1957, 1963a, 1963b, 1966, 1969; Boeckh et al., 1965), a brief summary of the status of published results will suffice here. Then I shall report in more detail the most recent advances we have made in studies of the ultrastructure of the receptor, the absolute threshold with the single receptor cell, the behavior of the animal, and finally the biochemistry of bombykol after it is adsorbed on the antenna.

Isolated male antennae, or antennae of mechanically immobilized male moths, respond with a slow electrical potential (electroantennogram = EAG) when stimulated with a puff of air containing bombykol. The stimulus normally induces a temporary negativity of the electrode situated at the distal end of the antenna. The EAG is assumed to be composed of a large number of receptor potentials of simultaneously stimulated bombykol receptors, which are arranged in the manner of serial electrical batteries.

Female antennae of *Bombyx*, or of any other moth so far tested, do not respond to bombykol or the lure gland. Female and male moth antennae, however, show EAGs when stimulated with other odorants.

Stimulus-response characteristics of the antennal receptor system were determined by a series of odor sources of rising strength. We loaded pieces of filter paper with different amounts of bombykol and put them in short glass tubes (cartridges). EAGs were elicited by blowing air through the tubes onto the antenna. The EAG-threshold concentration of bombykol administered in this manner was between 10^{-3} and $10^{-2} \mu g$. The response curve rises in proportion to the logarithm of bombykol concentration on the paper, and the functional range of the whole antenna covers a concentration ratio of 1:10⁵ or more (Schneider and Hecker, 1956; Schneider, 1957, 1962, 1963a, 1963b, 1966; Boeckh et al., 1965; Schneider et al., 1967; Schneider, 1967, 1969; Kaissling, 1969). Filter papers containing $100 \mu g$ or more of bombykol are "overloaded" because of their limited surface. These strong stimuli induce a marked adaptation of the responding system. Amplitudes of EAGs elicited with fresh female glands are equal to EAG responses of between 1 and 10 µg elicited by bombykol on filter paper (Steinbrecht, 1964a).

Stimulus-response curves to the bombykol isomers (10cis, 12-trans; 10-cis, 12-cis; 10-trans, 12-trans) are shifted to odor concentrations between 100 and 1000 times higher. In addition, these curves level off at submaximal amplitudes, thus showing "saturation" with strong stimuli (Schneider et al., 1967).

Earlier estimates of the absolute bombykol threshold led to values of approximately 10³ and 10⁷ bombykol molecules per cm³ of air for the behavioral and EAG responses, respectively (Boeckh et al., 1965; Schneider, 1967). The accuracy of our estimates was improved by the availability of tritiated bombykol and was later calculated as 10⁴ molecules per cm³ of air with 50 per cent of the animals responding (Schneider et al., 1968).

The sensory organs that are responsible for the reception of bombykol are long olfactory hairs (sensilla trichodea), according to microelectrode recordings (E. Priesner, unpublished; see also Boeckh et al., 1965; Schneider and Steinbrecht, 1968; Kaissling and Priesner, 1970). This finding corresponds to our observation with the wild silk moth, Antheraea pernyi, in which sensilla of this morphological type also responded to the attractant of the female (Schneider et al., 1964).

Structure of the Bombykol receptor

In earlier publications we described the histological structures of the *Bombyx* antenna as seen with the light microscope (Schneider and Kaissling, 1956, 1957, 1959). After the sensilla trichodea were identified as the bombykol receptor organs (Priesner, unpublished), their ultrastructure was studied with the electron microscope (Schneider and Steinbrecht, 1968; Steinbrecht, unpublished). The general scheme of such a sensillum is shown in Figure 1. Sensilla

FIGURE 1 Semischematic diagram in longitudinal section of a sensillium trichodeum of *Bombyx mori*. Only the base and the tip of the thick-walled sense hair are shown (approximately 25 per cent of total hair length). The hair is innervated by two sensory nerve cells which respond to the sexual attractant bombykol. Accessory cells and epidermis cells are omitted. The hair lumen is filled with a fluid, the "sensillum liquor," which bathes the dendrites. Inset: Enlarged area of the hair wall as seen with the electron microscope. *Abbreviations:* A, axon; C, cuticle; CS, ciliary zone of the outer dendrite; DS, extracellular sheath of the dendrites; IS, inner segment of the dendrite; L, sensillum liquor; OS, outer segment of the dendrite; P, pore; Pt, pore tubule; R, soma of the receptor cell. (Courtesy of Dr. R. A. Steinbrecht.)

trichodea are olfactory insect sensilla of the pore-tubule type. The cuticle of these organs is perforated by a complex system of outer pores and inner tubules which reach into the lumen of the hair. In the best-known sensillum of this type (the sensillum basiconicum of the carrion beetle: Ernst, 1969) it was shown that the pores and tubules are open to the outside, and that the inner end of the tubules is clogged by some electron-dense material. Despite claims of several investigators, these hollow structures are certainly not "neurofilaments" or fine protrusions of the dendrite that permit a direct cell contact with the air (see Ernst, 1969).

The dendrites of the sensillum trichodeum receptor cells are found in the lumen of the hair and are bathed in a liquid, the "sensillum liquor" (Ernst, 1969). Whether the tubules of the hair cuticle reach all the way to the cell membrane of the dendrite or end somewhere in the liquor is still an open question (Schneider and Steinbrecht, 1968; Steinbrecht, 1969b). Bombykol receptor hairs are between 45 and 140 μ in length, are innervated by one or two sensory nerve cells, and have 1000–3000 pores between 100 Å and 150 Å in diameter, with as many as 20,000 tubules approximately 200 Å in width. The receptor cell is of the ciliary type common to many insect receptors. The distal parts of the dendrites contain only small vesicles and neurotubules and contain no mitochondria or other cell organelles.

On the *Bombyx* antenna we found an average of 16,000 sensilla trichodea, which are supplied by one receptor cell or, at the most, two, amounting to a maximum of 32,000 bombykol receptor cells in one antenna, or 64,000 in both (Steinbrecht, unpublished). Eighty per cent, or 25,000, of these cells in each antenna are of the sensitive type, as described below (Kaissling and Priesner, 1970).

Counts of the $0.2-\mu$ -diameter axons in the antennal nerve revealed that each axon is connected directly with the deutocerebrum. Axon fusion, which was assumed to be the rule in afferent insect nerves, was not apparent in the *Bombyx* antenna and may be rare or nonexistent in insects (Steinbrecht, 1969a).

Preliminary histological inspection of the *Bombyx* deutocerebrum indicates that the number of neurons that are potentially the "secondary olfactory elements" is at least 100 times smaller than the number of odor receptor cells. This, together with the occurrence of glomeruli, which seem to be areas where the telodendrion of the receptor axons is in synaptic contact with the secondary cells, is strikingly analogous to the bulbus olfactorius of vertebrates.

Bombykol diffusion on and in the sensillum

The structural peculiarities of insect olfactory sensilla suggest that the stimulating molecules do not, as other investigators have thought (Slifer, 1961; Boeckh et al., 1965), pass

directly from the gas phase to the extended receptor surface. Instead, we now assume that the odor molecules are first adsorbed on the hair cuticle and thereafter diffuse through the pores and tubules into the lumen of the hair (Schneider and Steinbrecht, 1968; Adam and Delbrück, 1968; Ernst, 1969). Possibly they then continue to diffuse through the liquor before they eventually make contact with the dendritic membrane to start transduction by interaction with a hypothetical acceptor molecule. In principle, this system is analogous to the vertebrate nose (air passage, mucus, receptor hairs) and many other animal receptors, for instance, the vertebrate ear (pinna, outer canal, tympanum, middle ear, fluid, hair cells). In all these we are dealing with stimulus-conducting systems with potential filter qualities which may distort, select, and retard the stimulus before it reaches the transductor, the receptor cell.

This model of the olfactory sensillum is still hypothetical to a large extent, but for some of the critical steps we have direct or indicative evidence, which stems mainly from our studies with radioactive bombykol.

Adsorption on the cuticle of the hair is apparent when ⁸Hbombykol is blown on the antenna, where it is adsorbed readily and also quantitatively under physiological conditions. These measurements prove the correctness of earlier physical calculations (Adam and Delbrück, 1968) which predicted that the antenna, with its hairs arranged strategically, could filter the pheromone quantitatively out of the air stream. The assumption is inescapable that large parts of the hair surface are a catching area, because the threshold must be 1000 times higher if only the molecules that hit the pores directly are effective (Kaissling, 1969). The direct evidence of adsorption and the low threshold make obsolete our earlier considerations on a possible pore-hitting chance after molecule reflection or adsorption (see Boeckh et al., 1965).

Molecule transfer The next question is: How are the adsorbed molecules transferred to the dendrite? One possibility is a direct penetration of the cuticle, analogous to processes in the bombykol-producing gland of the female moth, which does not have pores, tubules, or any kind of canals (Steinbrecht, 1964b). A much more plausible assumption is that the bombykol molecules make use of the pore-tubule "gate-system" to enter the hair lumen. The structural geometry of this system strongly suggests such a process, which is also physically possible with a diffusion time which is short in relation to the reaction time of the cell (Adam and Delbrück, 1968; Kaissling and Priesner, 1970). Some of our experiments also indicate that a molecule-transfer system exists on the hair, the capacity of which may be a critical limiting factor. EAGs elicited by strong odor stimuli show long-lasting aftereffects which depend on the absolute stimulus strength and not on the stimulatory efficiency of a molecule, possibly owing to an overloaded sensillum surface, which slowly empties the adsorbed molecules through the tubules to the dendrite (Kaissling, 1969). So far, we still lack direct evidence that bombykol enters the pores and tubules, let alone that it diffuses through the liquor to the dendrite.

Another question is the location of the acceptor, which is generally supposed to be the sensitive and selective receiving structure, designed to "read" the message of the odor molecule (Kaissling, 1969). Again, the likely structure is the receptor membrane, the dendrite, which is, in all probability, also the locus of transduction. But we have no direct information on either the nature of the acceptor or its location. Could this critical deciphering system be situated somewhere between the hair cuticle and the membrane of the dendrite? Such a position is possible, if we assume, for instance, that the tubules are selective filters that are fully open for bombykol, partially open for the isomers, and closed for any molecule that is not eliciting a cell response. In that case, it would not be necessary for the membrane to be specialized for bombykol, but the membrane should be able to respond equally well to the isomers and some other molecules, because the tubules have already accomplished the selection. This somewhat provocative displacement of the specificity (away from the receptor cell membrane to an extracellular structure) is difficult to understand in view of the differentiating processes during morphogenesis, because the tubules are not the product of the receptor cell. Extracellular critical selection is also hardly understandable with all those insect olfactory sensilla, in which two or more cells with their dendrites share a common liquor space and have different reaction spectra for odorants (Schneider and Boeckh, 1962; Schneider, 1963a; Schneider et al., 1964; Lacher, 1964, 1967; Kaissling and Renner, 1968).

Finally, as with most other receptors, transduction in any olfactory cell is not understood. As with visual, auditory, and vibration receptors of extreme sensitivity, we must explain the function of a highly triggered system. A single odor molecule or very few can apparently start an explosive spreading of a permeability change or, in other words, induce the *receptor-generator potential*.

Threshold for the behavior and single-cell response

We have recently conducted new large-scale behavior tests and numerous single-cell recordings to improve the accuracy of our earlier estimates of the minimum number of molecules necessary to elicit a response (Kaissling and Priesner, 1970). Now, the prerequisite for an evaluation of these new experiments was the availability of radioactive bombykol. This compound was resynthesized, with one out of four molecules labeled with tritium in one of the cispositions (Kasang, 1968). We have now been able to measure the output of the bombykol sources, the cartridges, and to determine the amount of bombykol adsorbed on the antenna and on the hairs (Figure 2). As in our earlier work

FIGURE 2 Radiometric determination of molecule numbers on the antenna of *Bombyx*. Only the number of molecules on the filter paper $(3x10^{-6} \ \mu g \ bombykol)$ can be measured directly at the behavior threshold. All other values are extrapolations from measurements at higher intensities. See text for further explanations. (Courtesy of Dr. K. E. Kaissling.)

(Boeckh et al., 1965; Schneider et al., 1967), a direct measurement of the bombykol output was not possible with threshold stimuli, because the sensitivity of the receptor system of the animal is much greater than the sensitivity of the scintillation counter. The minimum amount of bombykol detected by the counter was the 10-second output of a cartridge holding $10^{-2} \mu g$. A significant number of animals (18 per cent beyond a control response of 5 per cent, with P = 0.002), however, reacted with wing fluttering if stimulated for less than one second by an air stream passing through a cartridge holding $3 \times 10^{-6} \mu g$ of bombykol, which can be called the behavior threshold (Figure 3, left curve).

For the extrapolation from the measured output down to the threshold output, we could rely on the observation that bombykol sources from 100 μ g down to $10^{-2} \mu$ g always gave outputs that were proportional to the load, and assume such a proportionality to be true also with the even smaller charges. With the extrapolation in time, we had to account for an initial output peak that bombykol sources show during the first 100 milliseconds after the onset of the stimulus.

After correcting for all these factors, including the molecules adsorbing on insensitive antennal structures, we found that, during a threshold stimulus, 300 bombykol molecules are available for the 25,000 receptor cells of one antenna. To learn the chances for hits of one, two, or more molecules on any of the cells, we applied the Poisson statistics. The result is that only two of the cells encounter two hits, and 300 encounter single hits (Kaissling and Priesner, 1970).

These findings have been decisively supplemented by single-cell recordings. The resting signal frequency of the receptor cells is low but not negligible: 25,000 cells send approximately 1600 impulses per second to the brain. One can predict that a minimum of 120 additional "bombykolimpulses" would be necessary to overcome this background noise.

What is the actual signal threshold of the single cells? Figure 3 illustrates the answer: with a $10^{-5} \mu g$ bombykol cartridge, few cells react with one impulse; a stimulus 10 times higher elicits one or more impulses in 30 per cent of the cells; two or more impulses in only a few cells; and so on. Because of the many measurements that led to these values, it can be said that the one- and two-impulse percentages are significantly positioned on Poisson curves that have been drawn through these points. Interestingly, the 10impulse curve does not correspond to the 10-hit curve.

The close correspondence of the theoretical Poisson

FIGURE 3 Bombyx mori male. Behavior reactions and nerve impulses of single receptor cells. Stimulus: bombykol in micrograms on the odor source (glass cartridge with filter paper, see Figure 2). Behavior reactions (left curve) counted during two seconds. Eighteen per cent of the animals (exceeding a control reaction by 5 per cent) react at $3x10^{-6} \mu g$ of bombykol (P = 0.002). The percentage of cells firing ≥ 1 and ≥ 2 impulses (hatched curves) fits the theoretical expectation of the corresponding Poisson distribution. The 10-impulse curves do not fit. Each impulse value is the mean of approximately 800 measurements. See text for additional explanations. (Courtesy of Drs. K. E. Kaissling and E. Priesner.)

curves with the increase of the number of responding receptor cells means that the average rate of impulses is, at these low stimulus intensities, strictly random and proportional to the stimulus strength. Impulse measurements necessarily failed to show a significant signal increase at the behavior threshold of $3 \times 10^{-6} \,\mu g$ of bombykol, because of the extremely reduced hit chance for a given sensillum from which one is recording. The precise correspondence of the impulse curves with the Poisson curves allows, however, an extrapolation to the range of the behavior threshold. Here we find that 200 impulses are elicited per 25,000 cells, a figure that, in the range of experimental error, is identical with the value of 300 cells as hit by one molecule each at the behavior threshold. This latter value stems from 3H-bombykol measurements, which also led to the conclusion that only two of all the cells of one antenna received two molecule hits each under these conditions. This then also means that only two of the cells gave two impulses each.

Bombykol adsorption in relation to structural geometry, cell number, behavior- and impulse-responses led to the conclusion that *single* bombykol *molecules elicit* at low stimulus intensities *single impulses* in the receptor cells. In order to reach the same response in 200 cells with double molecule hits, one would need a stimulus concentration 10 times higher. Therefore we may say that the most sensitive type of bombykol receptor cells "counts" the molecules at these low stimulus intensities.

Transduction and the fate of the bombykol molecule

According to neurophysiological knowledge, transduction in a receptor is understood as the transformation of the stimulus energy into the excitatory state of the cell. To analyze this process or the chain of processes in the case of the bombykol receptor, we need detailed information on the following:

- 1. The ionic composition of the dendritic cytoplasm and of the sensillum liquor.
- 2. The molecular composition and architecture of the membrane elements that maintain the membrane potential.
- 3. The chemical nature of the acceptor molecules that presumably interact with the bombykol molecules.
- 4. The mode of interaction between the acceptor and the bombykol.
- 5. The principle of the trigger which works on a quantal basis at low stimulus intensities: one molecule elicits one impulse, two elicit two impulses.
- 6. The fate of the bombykol molecule before and after the interaction.

Our extracellular electrophysiological recordings led to

the assumption that the receptor-generator potential is of dendritic origin, because the microelectrode which is placed at the hair base shows a relative negativity with excitatory stimuli. The polarity of the simultaneously recorded impulses, however, is usually positive, indicating that the impulses are a depolarization of the axon membrane near the basement membrane where the reference electrode is placed in the hemolymph (see Schneider et al., 1964; Boeckh et al., 1965). For a detailed insight into the effects of one, two, and more molecule hits, recording intracellularly is desirable, but at present this is hardly possible because of the small size of the cells. For the same reason, the chemistry of the dendrite and its extracellular and intracellular media is still unknown.

Recently Kaissling (1969) gave an interesting formalistic approach to the transducer function of the bombykol receptor. His calculations are based on the amplitudes and time constants of the rise and decay of the EAG, which is assumed to be a sufficiently reliable image of the receptor potential of the bombykol-transducing sensillum. In principle, the bombykol "bonding," which is thought to be responsible for the EAG, could be either an adsorptive or an enzymatic interaction. The calculation leads to an estimate of the number of bombykol acceptors, which is given as 10⁸ per antenna. Surprisingly, this figure is almost equal to the total number of tubules in all the bombykol receptor hairs. So far, we do not understand the meaning of this correspondence, but it indicates that the tubules may be responsible for the kinetics of the slow potentials.

The whole receptor system, with its huge branched antenna and long receptor hairs, is obviously designed for an optimal molecule-catching capacity. In contrast, the number of bombykol acceptors seems to be uneconomically low. If one speculates that the dendritic membranes are composed of medium-sized protein molecules, which are also the acceptors, one antenna would have between 10¹⁰ and 10¹² acceptors. One way to overcome this dilemma would be to assume that the tubules lead the molecules directly to the acceptor loci on the membrane, thus permitting the molecule to hit the right acceptor without delay. Unfortunately, micromorphological studies of these structures are extremely difficult, and one cannot as yet determine whether the tubules end directly on the membrane or somewhere in the liquor (see Figure 1).

Recently we have looked for the bombykol after exposing many antennae to tritiated bombykol for different periods of time (Kasang, unpublished). So far, the results indicate that bombykol is first adsorbed on the antennal surface. After several minutes, the bulk of the radioactivity has traveled into the antenna, whence it can now be eluated with strong organic solvents (chloroform-methanol). Interestingly, however, the radiochromatograms now show three fractions. The alcohol fraction, which presumably still is bombykol, is progressively metabolized into acid and ester.

There is no direct indication as yet that this process is related to transduction, because it is observed with male and female antennae and also occurs on other parts of the insect body (but not on cotton fibers).

This comparatively slow bombykol degradation, however, may very well be an important biological mechanism. The pheromone, aside from the question of whether it is used in transduction or only adsorbed on inexcitable structures, must become inactivated to prevent subsequent, and erroneous, receptor stimulation that may come from a later bombykol desorption. This consideration would, of course, also apply to the female. Female moths have been reported to be attractive only when their lure glands are expanded (Brady and Smithwick, 1968; Götz, 1951; Jacobson, 1965; Shorey and Gaston, 1967). Metabolic pheromone degradation would explain this phenomenon. Any attractant that also contaminates the scaly body of the calling female is progressively destroyed.

Summary

The sex-attractant (bombykol) system of the silk moth, Bombyx mori, consists of: (1) the female pheromone-emanating glands; (2) the transport medium (air); and (3) the receptor organs on the male antennae. The dendrite of the olfactory receptor cell is in a fluid-filled hair, the cuticular wall of which is penetrated by pores and microtubules. Bombykol molecules are adsorbed on the hair surface and presumably diffuse to and through the pores and tubules into the fluid, where they hit the dendritic membrane and elicit the cell response. Behavioral and electrophysiological threshold studies reveal that the receptor cell responds to single-molecule hits, whereas the animal needs the activation of approximately 200 cells in each antenna to start its motor response. The close correspondence of the impulses as elicited in the receptor cell, with the Poisson distribution of molecule hits, indicates that one molecule elicits one impulse and two molecules elicit two impulses. The 10-molecule hit curve, however, does not fit the 10-impulse curve. The mechanism of transduction is still unknown but can be treated in terms of a mathematical formalism which is based on the electrical responses. Biochemical studies indicate that bombykol is progressively, but only partially, metabolized into acid and ester on male and female antennae and on other parts of the body of the animals. Any connection between this process and the transducer function is so far unknown. The possible biological meaning of the bombykol degradation is discussed.

Acknowledgments

The observations, calculations, and speculations that are presented in this review are the results of the closely correlated teamwork of a group of scientists and technicians. The goal of our work is to analyze insect olfaction in general and bombykol reception in particular. Recently the latter complex of problems has been worked on successfully by Drs. K. E. Kaissling (physiology), G. Kasang (chemistry), E. Priesner (physiology), and R. A. Steinbrecht (histology). We are all indebted to our technical staff members (last but not least) for their skillful assistance.

47 General Principles of Neuroendocrine Communication

BERTA SCHARRER

ONE OF THE important insights gained in the neurobiological sciences during the past decade is recognition of the high degree of functional interdependence between nervous and endocrine centers. Their effectiveness in coordinating the body's regulatory activities requires pathways of communication between these two systems of integration (Figure 1). Because each of them functions in its own characteristic way, it cannot be assumed a priori that the "language" of one is suitable for the other. By definition, signals from endocrine organs to the nervous system are carried by blood-borne chemical messengers (hormones). In the framework of the present discussion, nothing more needs to be said about these afferent stimuli than that certain nerve cells are capable of recording endocrine signals and converting them into two types of neural activities. One leads to changes in the organism's behavior; the other elicits endocrine responses and thus becomes part of the ever-changing sequence of regulatory events that constitute neuroendocrine integration.

The nature of the efferent pathways, linking the neural with the endocrine apparatus, turns out to be rather complex. Its general analysis, which is the central topic of this chapter, is based on correlative structural and functional studies in a large variety of animal forms, both vertebrate and invertebrate. The literature in this field has become so voluminous that only a small selection of representative references can be given. The examination in depth of a few specific cases is the subject of the chapter that follows.

In principle, there are two ways in which the switchover from nervous to endocrine systems can be accomplished. One is by conventional innervation; the other, by the activity of specialized neurosecretory centers. The two modes of communication have certain features in common, but differ in others. In both instances, the neuron, in response to afferent stimuli, transmits information by means

BERTA SCHARRER Department of Anatomy, Albert Einstein College of Medicine, Bronx, New York of a special neurochemical mediator to an effector cell that is endowed with an appropriate receptor site. Major differences in the nature of the various available mechanisms concern the duration of the signal and the spatial relation between the site of release of the messenger substance and the receptor (effector cell).

FIGURE 1 Diagram illustrating theoretically possible neuroendocrine interactions. The arrows symbolize both nervous and hormonal connections. In any given case only some of the pathways are actually used. (From Scharrer and Scharrer, 1963.)

Control of endocrine cells by conventional innervation

Direct nervous control of endocrine cells by conventional synaptic transmission is feasible, as the recipient cell is geared to chemical mediation. However, the strictly localized nature of the contact areas involved, and the exceedingly short duration of the signals conveyed by standard neurotransmitter substances (e.g., acetylcholine, noradrenalin), impose certain restrictions on the efficacy of such a control mechanism. Optimally, every gland cell would have to be endowed with its own secretomotor junction. In order to result in appropriate responses, simultaneous and continuous signals would have to be directed, via these synaptic complexes, to the endocrine effector cells over periods of time that by far exceed those characteristic of regular interneuronal or neuromuscular communication. Therefore, the question is whether such conventional neural control, provided it exists in a given endocrine organ, plays a major or only a minor role.

An obvious feature to look for in organs suspected of being under direct neural control is morphological evidence of innervation. In the case of endocrine cells, secretomotor junctions have long been thought to be absent. Proof to the contrary was impossible under the restrictions of light microscopy. Even today, after much painstaking scrutiny of a variety of tissues under the electron microscope, neuroeffector junctions with endocrine cells have not been recorded with sufficient frequency to warrant the conclusion that each of these cells receives its own nerve supply, or at least the majority do. On this basis alone, therefore, it seems unlikely that all the existing neuronal directives, be they stimulatory or inhibitory, are conveyed to endocrine centers by conventional synaptic transmission.

Nevertheless, reports on ultrastructural evidence for innervation of endocrine cells are no longer a rarity, and cover a variety of organs. Among these, as might be expected, are effector cells of neural derivation, viz., those of the adrenal medulla (von Euler, 1967) and of the pineal gland (Wurtman et al., 1968; Machado et al., 1968). Neuroeffector junctions that establish contact with non-neural endocrine cells tend to lack some of the attributes of typical synapses, especially membrane specializations (see below). Such contact sites occur in beta and alpha cells of mammalian pancreatic islets (Legg, 1967; Esterhuizen et al., 1968; Watari, 1968; Shorr and Bloom, 1970); in all three layers of the adrenal cortex (Unsicker, 1969); in Leydig cells of the avian testis (Baumgarten and Holstein, 1968); and in the ultimobranchial body of amphibians (Robertson, 1967) and birds (Stoeckel and Porte, 1967), as well as in the parafollicular cells of a mammal (Young and Harrison, 1969). Control of the renin-producing juxtaglomerular cells by adrenergic fibers is suggested by fluorescence-histochemical

and electron-microscopic information (Barajas, 1964; Gomba et al., 1969). Of particular interest are data on the innervation of adenohypophyseal elements.

For example, in the pars intermedia of the cat (Figure 2, Figure 3A), Bargmann et al. (1967) observed one type of synaptic specialization, presumably adrenergic, with small, dense-core vesicles interspersed among electron-lucent ones (see also Streefkerk, 1967; Howe and Maxwell, 1968). Another, with only electron-lucent presynaptic vesicles, was tentatively interpreted as a cholinergic synapse but, like other secretomotor junctions in the endocrine system (Doerr-Schott and Follenius, 1969), these, too, might in reality be aminergic, even though they do not happen to display "typical" dense-core vesicles. The identification of adrenergic junctional complexes in the meta-adenohypophysis ("pars intermedia") of teleosts was accomplished by means of ultraradioautography after the administration of tritiated noradrenalin (Follenius, 1968). Several additional morphological data are available, for instance, for amphibians (Dent and Gupta, 1967; Jørgensen and Larsen, 1967; Enemar et al., 1967; Pehlemann, 1967; Saland, 1968; Goos, 1969).

Indirect experimental evidence for the existence of neural, as constrasted with hormonal, input was obtained from animals in which unilateral interruption of nerve supply affected merely one side of the neuroendocrine axis. This was true for the alteration of nuclear size in the zona fasciculata deprived of its connection with the ventromedial nucleus of the hypothalamus (Smollich and Döcke, 1969). In a comparable situation, among cephalopods, one of the existing pair of optic glands, the hormonal product of which stimulates gonadal maturation, was released from inhibitory neural control by unilateral severence of the connection with the central nervous system (Wells and Wells, 1969). Again, the result speaks for direct nervous control over endocrine tissue, even though the ultrastructural identification of regular secretomotor junctions is still missing (Bern, personal communication).

The question is what specific role can be assigned to synaptically transmitted information of this sort. In frogs, for example, aminergic light-dependent neurons in contact with pars intermedia cells seem to be responsible for a tonic type of inhibitory control over the release of the chromatophorotropin MSH (Oshima and Gorbman, 1969; see also Iturriza, 1969). Control over hormone release was also postulated for the adrenal cortex (Unsicker, 1969). On the whole, however, this question is still largely unanswered, because, in the majority of cases discussed in the preceding paragraphs, conventional synaptic signals are not the only controlling factors in operation. In fact, it would be difficult to state with certainty if, in any of the existing glands of internal secretion, conventional innervation would suffice as the sole means for control. As is discussed in the next section, the efficient operation of the neuroendocrine axis depends on the availability of additional mechanisms, which overcome the limitations inherent in synaptic control.

Control of endocrine cells by neurosecretory neurons

Neurochemical communication with endocrine structures in ways other than synaptic is accomplished by a special class of nerve cells called "neurosecretory neurons." An appreciation of their significance in neuroendocrine mediation requires a brief general characterization of the phenomenon of neurosecretion.

THE CLASSICAL CONCEPT OF NEUROSECRETION The concept that certain nerve centers specialize in "neurosecretory activity" has gradually evolved from a combination of cytological and physiological investigations. (For reviews, see Scharrer and Scharrer, 1963; E. Scharrer, 1965, 1966; B. Scharrer, 1967a, 1969a; Bern, 1966; Bern and Knowles, 1966; Picard and Stahl, 1966; Hagadorn, 1967a, 1967b; Bargmann, 1968; Hofer, 1968; Sachs, 1969.) Neurosecretory neurons are found widely in the animal kingdom, from primitive metazoans to mammals (Gabe, 1966; Lentz, 1968), which bespeaks their basic functional importance. In essence, the unique property of these neurons is that they produce chemical messengers in quantities that permit dissemination by circulatory channels. These substances, being more stable than regular neurotransmitters, are capable of eliciting sustained effects in multiple and diverse "target cells" that are situated at some distance from the site of release of the active principle. Many, but by no means all, of the responding cells are endocrine.

Because these blood-borne neurochemical messengers have a large sphere of operation, and because re-use of the mediator, as seems to occur in adrenergic and possibly other kinds of synaptic transmission by a "shuttle-service" type of operation (see Iversen, 1967), is unknown in neurosecretory substances, the latter must be synthesized in larger quantities than the conventional agents operating in "chemical synaptic transmission." In short, substances with the specifications outlined resemble regular hormones in every respect except that their cells of origin are neurons. The term "neurohormone" commonly applied to them is, therefore, indeed appropriate.

In cells manufacturing neurohormones, secretory activity takes precedence over other neuronal attributes. Thus, they are neither ordinary nervous elements nor glandular cells, but a combination of both (Figure 4). This structural and functional specialization sets them sufficiently apart from conventional neurons to warrant the designation of neurosecretory neurons (see B. Scharrer, 1967a, 1969a, 1969c).

Typical neurons of this kind are easily recognized at the

light- and electron-microscopic levels by their pronounced glandular features and the fact that, instead of establishing synaptic contact with contiguous (neuronal or non-neuronal) effector cells, they terminate in close proximity to vascular channels. The proteinaceous nature of the secretory product (active polypeptides bound to carrier proteins called neurophysins; see Berde, 1968) is responsible for its identification under the light and electron microscopes. The presence of characteristic, more or less electron-dense, membrane-bounded granules in several size categories has been demonstrated in numerous ultrastructural studies and need not be elaborated on here.

Groups of terminals laden with neurosecretory storage material, ready to enter the circulation, often form "neurohemal organs." These are exemplified by the neurohypophysis of vertebrates, the corpus cardiacum of insects, and the sinus gland of crustaceans. Together with the neural centers in which the neurohormones are manufactured and the axonal tracts in which they are conveyed to the terminals and stored, the neurohemal organs form neurosecretory systems.

The most widely studied among these organ complexes are the hypothalamic-neurohypophyseal systems of mammals and other vertebrates. The neurohormones released from them fall into two categories. 1. The so-called posterior-lobe hormones, derived from neurosecretory neurons in the supraoptic and paraventricular hypothalamic nuclei of higher vertebrates, reach nonendocrine "terminal targets" (such as kidney tubules and uterine muscles) by way of the general circulation. Their activities are examples of firstorder neuroendocrine mechanisms, a term proposed by Rothballer (1957) for neurohormonal activities that control "terminal targets" directly. Because they do not involve endocrine way stations, they lie outside the topic with which the present text is concerned. 2. Neurohormones originating in other hypothalamic centers, such as the arcuate nucleus, and released into the hypothalamic-adenohypophyseal portal system at the level of the median eminence are responsible for second- or third-order neuroendocrine mechanisms. These intrahypophyseal functions are of direct concern for processes of neuroendocrine interaction, and are discussed in somewhat more detail below.

In analogous organ systems among invertebrates, the central role of the neurosecretory neuron as an intermediary is essentially the same. It rests on its capacity to receive and process a variety of signals from neural centers and to pass it on to centers of internal secretion, thus exerting control over their multiple and intricate functions (E. Scharrer, 1952).

MODULATIONS OF THE CLASSICAL VIEWS ON NEURO-SECRETION The preceding paragraphs have summarized the classical interpretation of the phenomenon of neuro-

FIGURE 2 Diagram showing innervation of endocrine cells of pars intermedia of cat pituitary. Note presumed cholin-

ergic (1), adrenergic (2), and "peptidergic" (3) fibers and terminals. (From Bargmann et al., 1967.)

secretion. In recent years, important contributions to this core of knowledge have yielded new insights on two fronts, as a result of which the dividing line between conventional and neurosecretory neurons is no longer so sharp as it appeared in the past. Some of the existing borderline cases more or less defy classification, and the validity of criteria for the classification of neurosecretory neurons has changed.

1. In addition to the prototypes, i.e., the "peptidergic" neurosecretory A fibers, there are others in which the material to be discharged into the circulation or elsewhere is of nonpeptide character. Such B fibers (which should not be confused with the conventional neuron type for which the same letter is used in the neurophysiological literature) furnish active principles that resemble chemically those operating as transmitters in ordinary aminergic neurons, but do so in greater quantity and apparently with different results (see, for example, Knowles, 1965a, 1965b; Björklund et al., 1968; B. Scharrer and Weitzman, 1970). These elements are further discussed in the section on hypophysiotropic factors. The source of another kind of nonpeptide neurohormone may exist in the insect brain (Williams, 1967).

2. Not all the A and B fibers in existence terminate at or near vascular channels. They may establish direct contact with an effector cell which may be neuronal, endocrine, or neither. They may also terminate close to several putative effector cells, i.e., at a distance of no more than several thousand Ångstrom units. An extracellular stromal material that occupies the intervening space may perhaps serve as a tem-

porary reservoir and as a vehicle for the relatively slow propagation of the mediator substance (see Barer, 1967; B. Scharrer, 1969a).

Sites of direct contact ("neurosecretomotor junctions," Bern, 1966) and terminations close to endocrine cells can be found in the adenohypophysis of vertebrates and in analogous organs among invertebrates, such as the corpus allatum and the prothoracic gland of insects (B. Scharrer, 1964a, 1964b), and perhaps the infracerebral gland of nereids (Golding et al., 1968). Because, in such special instances, the dispatch of neurosecretory signals does not involve the circulatory system, and the action presumably occurs in the

direct vicinity of the site of release of the messenger substance, the latter should not be designated as a neurohormone. On the other hand, the proteinaceous nature of the mediator sets it apart from conventional neurotransmitters, and virtually nothing is known about the mode of operation of peptidergic neurosecretomotor junctions. Therefore, these cannot be ranked among the standard types of synaptic contacts, but rather among the "synaptoid" configurations (see below). The interpretation of this class of ultrastructural specializations has much to gain from the correlation of electron-microscopic and physiological information. This applies, for example, to the analysis of the events involved in the discharge of neurosecretory material from the axon, a problem that has been given much attention in recent years.

RELEASE MECHANISM FOR NEUROSECRETORY SUB-STANCES Irrespective of the nature of their site of termination, neurosecretory neurons display ultrastructurally distinctive areas at which the messenger substances are released (Figure 5). These subcellular specializations, which are rather widespread in the terminal part of the axon, mimic presynaptic parts of conventional interneuronal junctions (clustered "synaptic-type" vesicles, electron-dense deposits

Part of neurosecretory axon with three electron-dense granules, one of which faces a similar granule in extracellular location (arrow) (*Byrsotria fumigata*). \times 42,000. (A and B, from B. Scharrer, 1968a; C, original.)

at the junctional membranes, and so forth) and have, therefore, been called "synaptoid" configurations (see Knowles, 1967; Lederis, 1967; B. Scharrer, 1967b, 1968a).

At release sites where postsynaptic cells are missing (Figure 5), regular "chemical transmission" is out of the question. Therefore, the small electron-lucent vesicles in synaptoid areas need not be considered as receptacles for acetylcholine. Instead, at least some of them seem to be related to the mechanism by which the active material is released from the neurosecretory vesicle (see Knowles, 1965b; Bern, 1966; Herlant, 1967; Lederis, 1967; Streefkerk, 1967; Giller and Schwartz, 1968; B. Scharrer, 1968a).

More or less intact neurosecretory granules in extraaxonal location, i.e., having been discharged by exocytosis (Figure 5C) have been described in some species, particularly arthropods (see Weitzman, 1969; Normann, 1969). More often, however, the ultrastructural details observed speak for the fragmentation of the larger neurosecretory vesicles before their products are extruded from the neuron. In either case, the membranes bounding small synaptoid vesicles seem to be derived largely from those that formerly enclosed the neurosecretory granule (Figure 5B). It remains to be seen whether the more or less electron-lucent content of some of these small vesicles is active neurosecretory material that is no longer bound to its protein carrier and is ready to be discharged. Equally uncertain, therefore, is the chemical composition of the diffuse, electron-dense material that gives the impression of having been spilled from the neurosecretory vesicles and forms deposits close to the plasma membrane, ready to enter the extracellular compartment. Is it protein carrier (neurophysin) devoid of, or still affiliated with, active neurosecretory messenger substances? Further exploration of their mode of discharge and dissemination, the clarification of which is so important for the functional interpretation of these neurochemical mediators, should be based on the premise that one of several possible patterns may be prevalent, although not exclusive, in one animal species and absent or of minor importance in another.

The view that the synaptoid configurations discussed are indeed release sites of neurosecretory material is supported by experimental evidence. Their numbers were found to be increased after electrical stimulation in vitro of nerves, causing neurohormone release from the corpus cardiacum of insects (Scharrer and Kater, 1969; see also Normann, 1969). Because these more or less transient specializations of neurosecretory axons are functionally not equivalent to conventional synaptic elements, their presence is, in itself, not suggestive of impulse conduction. Nevertheless, the same mechanism, involving depolarization of the plasma membrane and calcium dependency, seems to be responsible for the transfer to the extracellular compartment of neurosecretory products, as well as other neurochemical mediators (Douglas and Poisner, 1964; Douglas, 1968).

HYPOPHYSIOTROPIC FACTORS Because of its dominant role in the control of other endocrine as well as "terminal" effector sites, the adenohypophysis and its dependence on neural input occupy the center of interest within the framework of neuroendocrinology (see Scharrer and Scharrer, 1963; Bajusz and Jasmin, 1964; Weitzman, 1964-1970; E. Scharrer, 1965, 1966; B. Scharrer, 1967a, 1968b, 1969a; Martini and Ganong, 1966-1967; Bajusz, 1969). Extrinsic and intrinsic afferent stimuli, transformed into uniform efferent commands within the hypothalamus, are relayed to the various glandular elements of the pars anterior and pars intermedia by neurochemical mediators, many of which qualify as neurohormones. These substances all have in common that they alter the release and apparently also the rate of synthesis of specific adenohypophyseal hormones. Instead of reaching their destinations by way of the general circulation, the hypothalamic factors involved make use of special pathways, in particular the primary plexus of the hypophyseal portal system.

Because a number of them elicit the discharge of adenohypophyseal tropic hormones, such as the follicle-stimulating and the adrenocorticotropic hormones, the former have been given the designation of "releasing factors." However, because this control over the pituitary by the central nervous sytem includes additional, e.g., inhibitory, activities, the more general terms of "hypophysiotropic factors" or "regulating factors" are preferable.

There is neither space nor need for a detailed discussion of the hypophysiotropic factors, which are referred to by abbreviations such as FSHRF (or FRF, follicle-stimulating hormone releasing, or regulating, factor). These have been extensively discussed and reviewed recently by several authors (see Schally et al., 1967–1968; Brodish, 1968; Mc-Cann and Porter, 1969).

The chemical nature of these relatively small molecules has not yet been entirely elucidated in mammals, and much less so in lower vertebrates (Jørgensen and Larsen, 1967). Most of them seem to be of peptide nature or, perhaps, of a more complex structure with peptide linkages (McCann and Porter, 1969). The existence of a carrier protein comparable to neurophysins of posterior-lobe material is suggested by the appearance of a histologically demonstrable substance that parallels an increase in CRF (corticotropin releasing factor) in the median eminence of the adrenalectomized mouse (Bock and aus der Mühlen, 1968).

There is, however, evidence for the presence of additional, i.e., nonpeptide mediators that are also released into the hypophyseal portal system of the median eminence. For example, in the rat, catecholamine-containing neurons (B fibers of Knowles) which form the tubero-infundibular tract, have been shown to participate in the regulation of gonadotropin secretion in a manner that has not, as yet, been fully clarified. There is some evidence that the time course characteristic for the operation of B fibers is intermediate between that of neurosecretory A fibers and conventional neurons. Perhaps such B fibers play an auxiliary role by monitoring the activity of peptidergic hypophysiotropic factors (Kamberi et al., 1969), or they may function as regulating factors in their own right.

The relevant principle involved in the control of rhythmic reproductive phenomena in the rat does not appear to be noradrenalin (Sandler, 1968) but dopamine, accumulations of which are present at terminal sites where release into the capillary plexus takes place. This class of materials can be demonstrated either histochemically by the highly specific fluorescence technique of Hillarp and his coworkers (see Falck and Owman, 1965), or electron microscopically by the presence of numerous small (about 500 Å), densecore vesicles after appropriate treatment (incubation with α -methylnoradrenalin, fixation in potassium permanganate).

The extensive analysis of Hökfelt (1967, 1968) deserves much of the credit for elucidating the ultrastructural criteria for aminergic release sites in this and other parts of the nervous system. His results are in line with those of Devine and Simpson (1968), Machado et al. (1968), Budd and Salpeter (1969), and others.

In mammals, the only known pathway for the neurochemical control of anterior pituitary cells, irrespective of the chemistry involved, is via the portal system just described.

The pars intermedia, on the other hand, shows peptidergic and aminergic terminals in direct contact with endocrine elements (Figure 2), as shown for the cat by Bargmann et al. (1967). Such junctional areas are also found on anterior pituitary cells of some fishes; in others, somewhat intermediate situations have been observed in which release sites of neurosecretory axons abut on the extracellular stroma discussed earlier (see Vollrath, 1967; B. Scharrer, 1968a, 1969b).

It is of particular interest that the mammalian pars intermedia, in addition to peptidergic neurosecretomotor contacts, also contains junctional complexes that possess the characteristics of conventional synapses (Bargmann et al., 1967). These are dealt with accordingly in the preceding section.

General conclusions and outlook

The general impression gained from this survey of neuroendocrine communication is that of a remarkable diversity by which neurons, both conventional and neurosecretory, address themselves to hypophyseal and other endocrine centers. Depending on the kind of animal and the glandular effector site under investigation, cellular conduction, diffusion, or vascular transport of the neuromediator may predominate. In other words, the transfer of information may occur at close contact or over a wide range of extracellular distances, and thus both neurohumoral and neurohormonal messengers are involved.

For the dispatch of localized signals, conventional "chemical synaptic" and special "peptidergic" junctions are available. The latter may provide relatively sustained "private" messages and thus overcome the temporal limitations of regular synaptic control. Yet, both forms of local signaling seem to have their place in special situations and, as they involve more than one type of chemical messenger, they can be said to enrich the "vocabulary" of neuroendocrine communication.

The fact remains, however, that the gap between the nervous and the endocrine systems could not be bridged effectively by conventional innervation alone. The major load in this important process is handled to best advantage by neurohormones, provided by neurosecretory neurons.

The realization that this distinctive class of neurons itself makes use of more than one chemical and functional type of neurochemical mediator has further widened the scope of the study of neuroendocrine mediation. As a result, an intermediate category of neuroendocrine interactions must now be recognized in which neither neurohormonal nor regular neurotransmitter-type messengers are in operation. These interactions, about which knowledge is still fragmentary, require much further illumination. A search along evolutionary lines should yield valuable information on the gradual evolvement of different levels of specialization and their functional significance. This phylogenetic process concerns not only a progressively restricted distribution of specific mechanisms for neurochemical signaling, but a concomitant increase in discrimination on the part of the effector cells. The biochemical background of this specialization is still in the realm of speculation. Although the common denominator in the different chains of cellular events elicited by various kinds of neurochemical mediators may be cyclic AMP (adenosine monophosphate) (Jutisz and Paloma de la Llosa, 1969), the specificity of the responding cell may have evolved in step with that of the enzyme adenyl cyclase, as suggested by Bonner (1969).

Irrespective of the existing spectrum of neuroendocrine mediation, the distinction between neurohormones and neurohumors should be retained. Similarly, the concept of neurosecretion should not be abandoned, in spite of recent modulations in its scope. On the other hand, the term "neurosecretory" would become meaningless if it were extended to include conventional neurons as well, even though they have the biosynthetic equipment for secreting small amounts of specific substances. This well-established term should continue to denote only that distinctive class of neuronal elements in which the synthesis, storage, and release of glandular products have become the dominant feature.

Hypothalamic neurosecretory neurons, together with the mammalian pineal and adrenal medulla, have been classified as "neuroendocrine transducers" by Wurtman et al. (1968), because they "act to convert a neural input into an endocrine output." In this respect, they are said to differ from "endocrine transducers (thyroid, ovary, adrenal cortex) whose physiological input comes only from the circulation." After careful assessment of current information, the question arises as to whether this classification is accurate and conceptually useful.

At first glance, the separate status of these three neuroendocrine transducers would seem to be justified, because it is concordant with the fact that, because of their neural derivation, they are singularly suited for neuroendocrine communication.

But what about endocrine glands of non-neural ancestry that display previously unsuspected signs of innervation? As discussed above, examples of these are found among various vertebrates in the pars intermedia and pars anterior of the pituitary, and adrenal cortex, the pancreatic islets, and in calcitonin-producing tissue; among invertebrates, an example is the corpus allatum of insects. Or, what about endocrine organs whose input of signals does not come from the circulation alone, but via additional pathways, such as extracellular stromal channels in the adenohypophysis of some fishes? Obviously, these and other cases do not fit into either of the two categories of transducers proposed by Wurtman.

Furthermore, is an endocrine effector cell that receives neurochemical instruction from a neurosecretory neuron an endocrine transducer if the mediator is a neurohormone? Does its status change to that of a neuroendocrine transducer if the message is conveyed by a representative of the same class of neurosecretory neurons, but in this case by way of a neurosecretomotor junction? In the latter instance, the neurosecretory neuron would be one step removed from the position of neuroendocrine transducer and would become the penultimate link in the chain of commands constituting neuroendocrine integration. Clearly, the multiplicity of existing and potential modes of operation does not lend itself to rigid categorization.

As it turns out, neuroendocrine "transduction" is not confined to the activity of modified neural elements capable of hormone production, but makes use of a whole spectrum of possibilities. The recognition of this versatility appears to be the salient feature in the present analysis of the subject of neuroendocrine communication.

48 Neuroendocrine Transducer Cells in Mammals

RICHARD J. WURTMAN

IN GENERAL, the brain sends signals to other organs by utilizing chains of neurons connected by synapses. Peripheral nerves constitute the last links in these chains; their axons terminate directly on skeletal muscle, adipose tissue, and exocrine glands, and transmit instructions to these cells by releasing acetylcholine or norepinephrine. Among the many tasks the brain must perform, at least two cannot be mediated solely through neuronal channels, because the organs with which the brain must communicate do not respond to neurotransmitters, which are released in their immediate vicinity, but to other chemical signals, which are delivered to them by the blood stream. These tasks include regulation of concentrations of certain substances in the extracellular fluid, and control of the reproductive organs.

For example, one of the effector mechanisms activated by the brain when plasma glucose concentrations fall below an allowable minimum operates by accelerating the rate of glycogenolysis in the liver. The immediate signal that instructs the hepatic cells to initiate the depolymerization of glycogen is a hormone, epinephrine, which reaches the hepatocytes not by diffusing across a synapse, but by being taken up from the circulation. Similarly, the brain of the female mammal instructs the ovary to mature, and subsequently directs it to ovulate, not by sending nerve impulses to individual ovarian cells but by causing the pituitary gland to secrete specific hormones, the gonadotropins. These substances reach the ovary via the blood stream, and activate biochemical processes leading to the maturation of the ovum, ovulation, and the synthesis of ovarian hormones.

The output signals emitted by neurons differ in important ways from those emitted by cells that communicate with their target tissues via the general circulation, i.e., endocrine cells. Hence, the ability of the mammalian brain to regulate substances in the extracellular fluid and to control gonadal function requires that the brain have access to a specialized group of communications cells capable of transducing neuronal inputs to hormonal outputs. These cells may be termed "neuroendocrine transducer cells." Their input signals resemble the input (or output) of a neuron, in that they respond to a neurotransmitter, which releases them by diffusing across a short distance, typically at a synapse. Their output signal is similar to the output (or input) of a true endocrine cell, in that they emit coded chemical messages that are delivered to all cells in the body, but provide information to only a relatively small population of receptor cells (Figure 1).

FIGURE 1 Schematic diagram showing inputs and outputs associated with neurons, neuroendocrine transducer cells, and endocrine cells.

The present paper compares some of the communications properties of neurons, endocrine cells, and neuroendocrine transducer cells, and describes two specific examples of the latter—pinealocytes and adrenomedullary chromaffin cells.

Some Differences Between Neural and Endocrine Communications

The transmission of signals from one neuron to another (or from a neuron to the cells that it innervates) is mediated by a familiar process: the neurotransmitter, a specific substance stored within characteristic subcellular vesicles, is liberated near the receptor cell. Most commonly, this release occurs at an identifiable anatomical locus, the synapse. The neuro-

RICHARD J. WURTMAN Massachusetts Institute of Technology, Cambridge, Massachusetts

transmitter then diffuses across a short distance to reach a specialized zone (the postsynaptic membrane) on the receptor cell, where it alters the flux of specific ions. This causes a change in electrical potential within the postsynaptic cell and, if the cell is a neuron, alters the probability that an action potential will be generated. Nearly all the compounds thought to function as neurotransmitters have similar chemical characteristics, i.e., low-molecular-weight, water-soluble amines and, possibly, amino acids. Moreover, they are rapidly inactivated by physical and chemical processes such as reuptake into their cell of origin or enzymatic transformation. Their concentrations in the blood tend to be very low.

The transmission of signals between organs via the blood stream utilizes an array of chemicals far broader than the current list of putative neurotransmitters; furthermore, the hormones seem to lack common chemical characteristics. Thus, insulin is water-soluble, but progesterone is highly nonpolar; thyroxine is a low-molecular-weight amino acid, but thyroid-stimulating hormone (TSH) appears to be a large glycoprotein; epinephrine is rapidly cleared from the circulation (by enzymatic transformation or uptake into sympathetic nerve endings), but cortisol persists in the blood for relatively long periods. The specific anatomic locus on the receptor cell at which a hormone acts has yet to be identified, and almost certainly lacks the well-defined structural features of the postsynaptic membrane. Similarly, no characteristic electrical response has been identified in hormoneresponsive cells analogous to the ion fluxes and potential changes observed in the postsynaptic neuron or at the neuromuscular junction. Within seconds one can usually tell whether a given neuron has received and responded to a neurotransmitter; considerably more time is required to determine whether a thyroid cell has responded to circulating TSH.

Perhaps the most characteristic difference between the transmission of signals by neurotransmitters and that by hormones lies in the techniques used by these communications systems to attain "privacy." Nervous systems obtain privacy by anatomical means: a given neuron apparently transmits signals only to the small number of cells with which it makes synapses, or to cells lying within a few hundred Ångstroms of its terminal boutons. Thus, even though the particular chemical signal (e.g., acetylcholine) emitted when a particular neuron fires might be capable of stimulating 10⁸ other neurons within the brain, only 10² or 10³ cells respond, because only this smaller number of neurons actually receives quanta of the neurotransmitter.

Communications systems that utilize the circulation to transmit signals obtain privacy by biochemical means: a given signal may be distributed by the blood to every cell in the body; the signal is, however, coded, and only a relatively small number of cells are able to perform the necessary decoding operation to obtain information. The high degree of specificity attainable by hormonal communications systems is well illustrated by the physiological regulation of the thyroid gland. TSH, the input to this organ, is carried by the circulation to every organ in the body; thyroxine, its output, is distributed in essentially the same volume. However, only the thyroid gland appears capable of responding to the information content in circulating TSH levels, while the heart, the liver, and most other organs show biochemical responses to circulating thyroxine.

Table I describes some characteristic differences in the ways signals are transmitted by neurons and glandular cells.

	Table	Ι
--	-------	---

Information Transfer Via Neurons	and Ena	locrine Cells
----------------------------------	---------	---------------

	Neurons	Endocrine Cells
Primary input	Neurotransmitter at synapse	A hormone or other blood-borne substance (no characteristic locus of input)
Responses	Fast: Release of neurotransmitter	Fast: Release of hormone
	Slow: Synthesis of specific neuronal proteins	Slow: Effects on glandular structure
Output:		
Language	Few words: com- pounds of low molecular weight, high polarity, similar structure	Large vocabulary; wide range of molecular species
Distribution	Local	General
Privacy	By anatomy	By biochemical coding
Extinction	Rapid	Slower

Neuroendocrine Transducer Cells

The conversion of neural to hormonal signals is accomplished by a third group of communications cells, the neuroendocrine transducers (Wurtman and Axelrod, 1965). As do neurons and endocrine cells, the neuroendocrine cells transmit messages from one locus within the body (i.e., the cells that provide their input) to specific groups of receptor cells. Data available on the input signals to several specific neuroendocrine transducers suggest that these cells respond to typical neurotransmitter substances (acetylcholine and norepinephrine), which reach them by diffusing across synapses or from nearby boutons. Their output signals exhibit all the variety typical of hormones: epinephrine is water-soluble, but melatonin is nonpolar; renin is a high-molecular-weight protein, but epinephrine and melatonin are low-molecularweight derivatives of single amino acids. The output signals (the hypophysiotropic hormones) emitted by hypothalamic

transducer cells, which mediate the neural control of the anterior pituitary, apparently act only on this single target organ. In contrast, oxytocin, a hormonal signal emitted by the paraventricular nucleus, carries instructions to both the uterus and the myoepithelium of the mammary glands.

The demonstration that a given cell functions as a neuroendocrine transducer requires two types of evidence: (1) it must be shown by anatomical methods that the cell receives a direct innervation; and (2) it must be demonstrated that the ability of the cell to secrete its hormone under appropriate physiological conditions is impaired on interruption of this innervation. With these criteria, at least five groups of cells can now be termed neuroendocrine transducers. They are:

- 1. The chromaffin cells of the adrenal medulla, which respond to a sympathetic cholinergic input by releasing the hormone epinephrine (Wurtman, 1966).
- 2. The parenchymal cells of the mammalian pineal organ, which respond to a sympathetic noradrenergic input by synthesizing and releasing the hormone melatonin (Wurtman et al., 1968).
- 3. The cells of the supraoptic and paraventricular hypothalamic nuclei, which respond to noradrenergic or cholinergic inputs, or both, by releasing the hormones vasopressin and oxytocin (Scharrer and Scharrer, 1963).
- 4. Hypothalamic cells which may reside within the arcuate nuclei and which appear to secrete "releasing factors" or hypophysiotropic hormones into the pituitary portal circulation, possibly in response to a noradrenergic or dopaminergic input (Martini and Ganong, 1967).
- 5. The juxtaglomerular cells of the mammalian kidney, which respond to a sympathetic noradrenergic input by releasing renin into the blood stream (Bunag et al., 1966).

It seems likely that this list will continue to expand. Whenever it can be demonstrated that the brain influences the secretion of a hormone from a peripheral organ (e.g., insulin from the pancreas), a *prima facie* case has been made for the participation of a neuroendocrine transducer in the secretory process.

Neuroendocrine transducer cells in the adrenal medulla and the supraoptic nucleus contain characteristic granular vesicles visible by electron microscopy, segregated by ultracentrifugation, and shown by chemical or biological assays to store the secretory products of their respective cells. On the other hand, pincal parenchymal cells do not seem to store their secretion in a characteristic organelle. Hence, the tendency for the secretion of a cell to be localized within a visible particle cannot be used for the identification of neuroendocrine transducer cells. This tendency seems to be correlated with the chemical nature of the secretion and not with the communications properties of its cells of origin. Water-soluble hormones are often present in relatively high concentrations within their cells of origin. Their partial confinement within vesicles allows these concentrations to exist without unduly raising the cytoplasmic solute loads. Moreover, the binding of epinephrine and insulin to subcellular particles probably protects these hormones from catabolic intracellular enzymes (i.e., mitochondrial monamine oxidase and lysosomal proteases), which would destroy them if they floated freely in the cytoplasm. Lipid-soluble hormones tend not to be localized within vesicles or similar subcellular particles. For example, estrogens and thyroxine are stored in reservoirs outside the cell, that is, in the follicular fluid of the ovary or the colloid of the thyroid, whereas corticosterone is probably synthesized *de novo* on demand.

The Chromaffin Cells of the Mammalian Adrenal Medulla as Neuroendocrine Transducers

The adrenal medulla, situated outside the cranial cavity, is considerably more accessible for study than the neuroendocrine transducers of the pineal and the hypothalamus. The adrenal vein can easily be cannulated, and the epinephrine and norepinephrine in venous blood can be measured in response to altered physiological states or to the stimulation of the splanchnic nerve that innervates the adrenal.

The adrenal medulla is probably the sole source of circulating epinephrine in mammals (Wurtman, 1966). This unique ability to synthesize and secrete the catecholamine derives from the fact that the adrenal chromaffin cells contain almost all the enzyme phenylethanolamine-N-methyl transferase (PNMT) that is present in adult mammals (Figure 2). (Small amounts of PNMT activity can be demonstrated in parts of the brain [Pohorecky et al., 1969]; however, it is unlikely that significant quantities of unchanged epinephrine enter the blood stream from this organ.) PNMT catalyzes the transfer of a methyl group from S-

FIGURE 2 Biosynthesis of epinephrine in mammalian adrenal medulla. The N-methylation of norepinephrine is catalyzed by the enzyme phenylethanolamine-N-methyl transferase (PNMT).

adenosylmethionine to the amine nitrogen of norepinephrine (Axelrod, 1962).

Specific mechanisms exist for controlling both the chemical nature of the material secreted by the adrenal medulla and the net rate of secretion:

1. At any given time, the percentage of epinephrine in the total amount of catecholamine secreted depends on a hormonal factor, i.e., the delivery of glucocorticoid hormones secreted by the adrenal cortex to the medullary chromaffin cells (Figure 3). The steroid hormones elevate PNMT activity, probably by accelerating the synthesis of the enzyme protein (Wurtman and Axelrod, 1966). If adrenocortical secretion is suppressed by the removal of the pituitary gland, both PNMT activity and the ratio of epinephrine to total adrenal catecholamines fall. This ratio in the adrenal venous effluent also declines (Wurtman et al., 1968c), inasmuch as the chromaffin cells appear to secrete epinephrine and norepinephrine in roughly the same proportions as they store them. The administration of small amounts of adrenocorticotrophic hor-

FIGURE 3 Control of the synthesis and secretion of epinephrine in the mammalian adrenal medulla. The synthesis of epinephrine (E) from norepinephrine (NE) is catalyzed by the enzyme phenylethanolamine-N-methyl transferase (PNMT), which is induced by glucocorticoid hormones secreted from the adrenal cortex (e.g., hydrocortisone, corticosterone). These compounds are preferentially delivered to the medullary chromaffin cells by an intra-adrenal portal venous system; their secretion is stimulated by a hormone (adrenocorticotrophic hormone, ACTH) from the pituitary gland. The secretion of epinephrine is stimulated by preganglionic cholinergic neurons, the terminal boutons of which form synapses with the adrenal chromaffin cells.

mone (ACTH), or of very large doses of natural or synthetic glucocorticoids, restores PNMT activity (and the in vivo synthesis of epinephrine) in hypophysectomized animals (Table II). This high glucocorticoid requirement

TABLE II

Effect of Hypophysectomy and ACTH on Phenylethanolamine-N-Methyl Transferase Activity

	PNMT Activity			
Treatment	mµM/gland	mµM/gm		
Normal	123.1*	122.3*		
Hypophysectomized	28.8	43.1		
Hypophysectomized + ACTH	190.0*	147.3†		

*P < 0.001 differs from hypophysectomized.

 $\dagger P < 0.01$ differs from hypophysectomized.

is not surprising, for it is known that the adrenal medulla is normally perfused with glucocorticoid concentrations 100 to 1000 times greater than those present in peripheral blood. The adrenal chromaffin tissue of mammals is surrounded by an envelope of adrenal cortex, and preferentially receives the undiluted secretions of this layer via a portal vascular system (Coupland, 1965). Treatment of hypophysectomized animals with low doses of ACTH restores the preferential delivery of adrenocortical steroids to the medulla. Doses of glucocorticoids that restore the levels of hydrocortisone in peripheral blood to normal fail, however, to replace the hormone levels normally available to the medulla.

It is interesting to note that in the frog—an animal in which PNMT activity and epinephrine are found in many organs and in which epinephrine may function as a neurotransmitter—the adrenal gland lacks a well-defined cortex and medulla and PNMT activity is not modified by hypophysectomy, nor is the enzyme protein induced by treatment with glucocorticoids (Wurtman et al., 1968b). The adrenal medulla as a neuroendocrine transducer is probably a phylogenetically new organ in mammals.

2. The release of epinephrine (or norepinephrine) from the adrenal medulla is stimulated by nerve impulses delivered to the chromaffin cells by the cholinergic terminals of the splanchnic sympathetic nerves (Figure 3). Physiological stimuli, such as hypoglycemia, which normally accelerate epinephrine secretion, fail to do so if the medulla is denervated, or if the animal is treated with cholinergic blocking agents.

The hormonal signal represented by epinephrine can be decoded by a relatively large number of target cells. For example, epinephrine release accelerates hepatic glycogenolysis, stimulates the rate and force of cardiac contraction, and suppresses the insulin secretion from the beta cells of the pancreas.

Mammalian Pinealocytes as Neuroendocrine Transducers

NEURAL AND PHOTIC REGULATION OF MELATONIN SYN-THESIS In mammals, the parenchymal cells of the pineal organ are unique in their ability to synthesize melatonin and other methoxyindoles (Figure 4). This characteristic results described below indicate that in the pineal, as elsewhere, the catecholamine is the true sympathetic neurotransmitter; the presence of serotonin within the nerve terminals probably results from the extremely high concentrations of the indoleamine in the neighboring pineal parenchymal cells.

Nerve impulses generated in rats when they are exposed to light apparently *decrease* the flow of action potentials to the pineal gland; hence, less of the sympathetic neurotransmitter is liberated. Within the parenchymal cells, HIOMT activity falls, and the rate of melatonin synthesis declines. If

FIGURE 4 Biosynthesis of serotonin and melatonin in the mammalian pineal organ. The transfer of a methyl group from S-adenosylmethionine

to the 5-hydroxy position of N-acetylserotonin is catalyzed by the enzyme hydroxyindole-Omethyl transferase (HIOMT).

from the highly specific localization of the enzyme hydroxyindole-O-methyl transferase (HIOMT) to these cells (Axelrod et al., 1961). HIOMT catalyzes the transfer of a methyl group from S-adenosylmethionine to hydroxyindoles such as N-acetylserotonin (Figure 4). Environmental lighting indirectly controls its activity. In rats, exposure to light generates nerve impulses that travel to the pineal organ by a complex pathway, including the retina, the optic nerves and chiasm, the inferior accessory optic tract, the medial forebrain bundle, descending neurons that mediate the central control of sympathetic nervous function, preganglionic fibers from the cervical spinal cord to the superior cervical ganglia, and postganglionic fibers that terminate in the vicinity of, or directly upon, pineal parenchymal cells (Figures 5A, B, and C, pages 536 and 537; Table II) (Wurtman et al., 1968a). The terminal boutons of pineal sympathetic nerves are unique in that their storage vesicles contain serotonin as well as norepinephrine. In vitro studies

one blinds the rats, or blocks the photic input to the pineal by transecting the inferior accessory optic tracts or by removing the superior cervical ganglia, HIOMT activity within the gland no longer responds to changes in the photic environment. This dependence on an indirect, nervous pathway for its photic input constitutes a major difference between mammalian pineal organs and the photoreceptive pineals of such lower vertebrates as the frog (Rana pipiens). Pineal cells in this species contain characteristic outer segments; these transduce light energy of specific wavelengths to nerve impulses, which are then transmitted directly to the brain. In mammals, pineal organs lack photoreceptive elements and cannot be shown electrophysiologically to respond directly to light. Moreover, they neither send axons to the brain nor receive a central innervation. The functions of melatonin also appear to have changed with evolution. In the frog, HIOMT activity is demonstrable in the pineal, but the enzyme is also present in the brain and elsewhere.

The distribution of HIOMT is compatible with the hypothesis that its product, melatonin, functions as a neurotransmitter rather than as a hormone. In mammals, the pineal gland is the sole site of melatonin synthesis; the indole is synthesized and probably released as a hormone in response to sympathetic nervous inputs.

THE EFFECTS OF NOREPINEPHRINE ON MELATONIN SYN-THESIS The regulation of pineal function by suggested neurotransmitters can be studied in vitro: If individual organs are incubated with ¹⁴C-labeled tryptophan, they convert the amino acid to ¹⁴C-serotonin, ¹⁴C-melatonin, and ¹⁴C-5-hydroxyindole acetic acid (5-HIAA), which are released into the incubation medium; they also synthesize and store ¹⁴C-labeled proteins. These processes proceed linearly for at least 48 hours and show surprisingly little variation from one pineal organ to another. Compounds thought to be candidates for the sympathetic neurotransmitter substance in the pineal can be added to the medium in various concentrations, and their effects on indole and protein synthesis can be examined.

The addition of L-norepinephrine and related catecholamines to the incubation medium causes a marked increase in the amounts of ¹⁴C-melatonin and ¹⁴C-serotonin synthesized and released into the medium (Axelrod et al., 1969) and smaller increases in the amounts of ¹⁴C-protein and ¹⁴Ctryptophan accumulated within the pineal organ (Wurtman et al., 1969). The increase in ¹⁴C-protein content probably depends on a pool effect, i.e., norepinephrine increases the uptake of labeled tryptophan from the medium, causing its specific activity within the cell to rise. The much greater effect of the catecholamine on 14C-melatonin synthesis almost certainly results from an action on the biosynthetic pathway connecting serotonin and melatonin. This explanation is supported by the observations that the addition of norepinephrine to the medium also causes increased HIOMT activity assayed in vitro. The addition of serotonin to the incubation medium has no effect on ¹⁴C-melatonin synthesis, nor does this amine modify the responses of the culture to added norepinephrine. These data support the hypothesis that norepinephrine, not serotonin, is the neurotransmitter released from pineal sympathetic neurons.

The role of the adenyl cyclase system in the effects of norepinephrine of the pineal has recently been examined by using dibutyryl-3'-5'-adenosine monophosphate (DAMP), a synthetic derivative of cyclic AMP (Shein and Wurtman, 1969). The addition of relatively small amounts of this substance to cultured pineal organs mimics the stimulation of ¹⁴C-melatonin and ¹⁴C-serotonin synthesis produced by norepinephrine (Table III). However, dibutyryl-AMP does not increase the accumulation of ¹⁴C-trytophan or of ¹⁴Cprotein within pineal cells (Wurtman et al., 1969). Because norepinephrine has indeed been shown to enhance the activity of adenyl cyclase (a membrane enzyme) in pineal homogenates, this dissociation of indole synthesis from tryptophan uptake is compatible with the general hypothesis that cyclic AMP mediates *some* of the biochemical effects of norepinephrine, e.g., those affecting processes within the cytoplasm of the cell, but does not mediate the direct effects of the neurotransmitter on cellular membranes, e.g., the stimulation of ¹⁴C-tryptophan uptake.

The complete demonstration that mammalian pineal cells function as neuroendocrine transducers would require evidence that the sympathetic nervous input to these cells accelerates both the synthesis and the secretion of melatonin. Unfortunately, it has not yet been possible to study the rate of melatonin release in vivo. It is clear that melatonin is released from the pineal, for the indole is present in the urine and in tissues such as peripheral nerve, which lack HIOMT activity. It is, however, undetermined whether the indole is secreted into the general circulation as are most other hormones, or released directly into the cerebrospinal fluid. Teleological considerations, if not experimental evidence, support the latter possibility. Melatonin apparently produces its biological effects in mammals by acting on the brain. Isotopic studies have shown that the likelihood that a given molecule of melatonin can gain entry to the brain is almost 100-fold greater if it is placed in the cerebrospinal fluid than if injected into the blood stream. Methods must be developed for collecting the output of the pineal and assaying this material for melatonin, before it can be claimed with certainty that pineal cells are true neuroendocrine transducers.

Summary

The three kinds of mammalian cells specialized to transmit signals from one organ to another are neurons, neuroendocrine transducer cells, and endocrine cells. Neurons and neuroendocrine transducer cells respond to neurotransmitter inputs, which usually reach them at synapses; the signals emitted by neurons are also neurotransmitters. The hormonal signals released by neuroendocrine transducer cells and

endocrine cells are coded and complex chemicals distributed throughout the body by the general circulation; the inputs to endocrine cells are also hormones. Neural communications links attain privacy by anatomical means, i.e., they transmit signals only to cells that lie close to their terminal boutons. Endocrine communications systems attain privacy by chemical coding: their output is distributed universally, but only a relatively small population of cells is able to decode their message. Examples of neuroendocrine transducer cells include mammalian pinealocytes, mammalian adrenomedullary chromaffin cells, the "hypophysiotropic" cells of the hypothalamus, the cells of the supraoptic and paraventricular nuclei, and the juxtaglomerular cells of the kidney.

49 The Olfactory Bulb as a Simple Cortical System: Experimental Analysis and Functional Implications

GORDON M. SHEPHERD

NEUROBIOLOGISTS ARE INTERESTED in the mammalian olfactory bulb for two main reasons. One is its obvious importance for olfactory discrimination. Less obvious is its relevance to the study of what may be called "cortical systems." It is, however, from this latter point of view that I wish to describe the experimental analysis of neuronal interactions in the olfactory bulb. This work has suggested a general scheme for the organization of neuronal systems within the bulb (Phillips et al., 1963; Shepherd, 1963b), and it has provided the physiological data for the theoretical analysis, described by Rall elsewhere in this volume, which predicted a dendrodendritic synaptic pathway for recurrent inhibition through the amacrine-type granule cells of the bulb (Rall et al., 1966; Rall and Shepherd, 1968). My aim is to describe what we now know about the neuronal organization of the bulb, to outline where we stand with regard to experimental evidence for the functional properties of granule cells, and to indicate some implications for our understanding of neuronal integration in the bulb and in other cortical systems in the central nervous system.

We may begin by defining a "cortical system" as a region of the central nervous system that has the following characteristics. The neurons are differentiated into several distinct types, and their cell bodies and cell processes are organized into several nonrepeating layers. One type, which may be designated as the output neuron, is large; its processes span most of the layers, and it sends its axon to other parts of the CNS. There is also usually a free surface. This definition includes regions as diverse as neocortex, cerebellum, hippocampus, prepyriform cortex, olfactory bulb, and, as I show below, retina; it generally excludes spinal, brain stem, and thalamic relay nuclei. By this it is not meant to imply that many of the neuronal mechanisms in cortical regions are not similar, in principle, to those in the relay nuclei; what is implied is that, in the course of vertebrate evolution, particular demands have arisen for the processing and retention of information, perhaps within certain spatial constraints placed on the brain, and these demands have been met by a "cortical" organization.

If it be accepted that there are common principles of neuronal organization for the processing of information in parts of the vertebrate brain that have a cortical organization, then attention is naturally directed to cortical regions with the simplest construction, providing thereby the best hope for unambiguous physiological results. Among cortical regions, as above defined, the olfactory bulb is noteworthy for its simple and symmetrical organization. Moreover, it is one of the first cortical structures to emerge in the course of vertebrate evolution, and certain features of its organization are clearly recognizable throughout the vertebrate series. Within the bulb are several distinct neuronal types, the dendrites and axon collaterals of which are restricted to an unusual degree to different layers. These features, and others that are pointed out below, suggest that the olfactory bulb may be viewed as a "reduced" or simplified cortical system, an E. coli for cortical physiology, one might say, and it is from that point of view that our experiments have been undertaken.

Anatomy of the bulb

The anatomical features of interest to the experimenter are illustrated in Figure 1. At the top is a drawing of the head of a rabbit; the olfactory bulb is situated in front of the forebrain, and is easily exposed for the purpose of recording with micropipettes simply by removing the overlying layer of bone. The main input to the bulb is by way of the bundles of olfactory nerve fibers from the nose; the main output is by way of the lateral olfactory tract on the surface of the prepyriform cortex of the brain.

The bottom diagram in Figure 1 represents Golgi-stained neurons from the layers in the dorsal part of the bulb. The neuron of first importance is the mitral cell; it sends out a primary dendrite to receive the input from the olfactory nerves coming from the surface of the bulb, and its axon is directed deeply and emerges posteriorly to form the lateral olfactory tract. Our basic experimental procedure (Phillips et al., 1963) was to place a fine stimulating wire on the ex-

(Modified from Allison, 1953.) Bottom: Golgi-stained neurons in bulb. Olfactory nerve fibers enter from dorsal surface, above. *Cell types:* G, granule; M, mitral; T, tufted. (Modified from Ramón y Cajal, 1911.)

posed tract and send single volleys of impulses into the bulb; there the volleys invade the mitral cells directly and synchronously in the antidromic direction. Another wire was placed on a bundle of olfactory nerve fibers, so that single orthodromic volleys could be set up (Shepherd, 1963a), and these caused synchronous synaptic activation of the mitral cells through the mitral primary dendrite.

It should be appreciated that the bulb can be activated over input and output pathways that are completely separated from each other, so that there is no danger of affecting the one when stimulating the other. In addition, the pathways form discrete bundles and are therefore easily stimulated, and they lie fully exposed on the brain surface so that the stimulation is always under direct visual control. The separation of input and output pathways for the mitral cell is almost as complete as for the motoneuron in the spinal cord; the only qualification is the possibility of centrifugal fibers in or near the lateral olfactory tract at the point of stimulation (Ramón y Cajal, 1911; Heimer, 1968; Price, 1968).

These experimental advantages are unusual for a cortical structure in the CNS, and they are matched by some un-

usual characteristics of the neurons themselves within the bulb. The neurons are differentiated into several distinct types, and, most importantly, their processes are restricted to clearly defined layers. Thus, the olfactory nerve fibers all terminate in a single layer of rounded structures called glomeruli, a feature of all vertebrate olfactory bulbs from the lamprey to man. The mitral cell bodies all lie deeper, in a separate layer. The consequence of this arrangement is that the only way the olfactory nerve input can set up impulses in the mitral axons is through the mitral primary dendrite. Thus, as Ramón y Cajal (1911) stressed, the mitral primary dendrite is unique proof, on anatomical grounds alone, that dendrites in the CNS can play an essential role in transmitting nerve signals, rather than being limited to serving long-term or metabolic functions. The primary dendrite has a radial orientation and spans the entire external plexiform layer; in the young rabbits that we used its minimal length was 400–500 μ and its average diameter was of the order of 6μ .

The mitral cell also gives rise to several secondary basal dendrites which run laterally in the external plexiform layer. Their branches are entirely confined within this layer, which means that they are functionally isolated from the glomerular input and form a second, separate, dendritic field for the mitral cell. This is one of the clearest instances of what may be termed "fractionation of dendritic field" (cf. Sprague, 1958) in the CNS, the significance of which is mentioned below. The mitral axon gives off two kinds of collateral: deep ones directed laterally, and recurrent ones which run radially and terminate in the external plexiform layer. Ramón y Cajal suggested that the recurrent collaterals would provide for "avalanche conduction" by connections with neighboring mitral cells; our evidence for their action is discussed below.

Although the mitral cell is the primary output neuron of the bulb, the most numerous neuron is the granule cell. These have small cell bodies which lie in clusters below the mitral cell body layer. They give off a short central dendrite and a long peripheral dendrite which branches and terminates in the external plexiform layer. The dendritic branches are covered with gemmules (spines), resembling thereby the apical dendrites of cortical pyramidal cells; in contrast, the mitral dendrites are smooth, like motor-neuron dendrites. In specimens fixed in Bouin's fluid and stained with cresyl violet (Shepherd, 1966), the mitral dendrites are clearly apparent, but the granule dendrites (like cortical pyramidal dendrites) are not clearly seen. Thus, two distinctive types of dendrite seem to be intermingled in the external plexiform layer.

The classical Golgi studies were in agreement that the granule cell lacked an axon and was analogous in this respect to the amacrine cell in the retina. Ramón y Cajal supposed the peripheral process to carry activity in a cellulifugal direction; although he could draw no further functional implication, he was impressed by the "absolute constancy of the connections between the granule cell processes and the mitral secondary dendrites in the external plexiform layer" (Ramón y Cajal, 1955). The evidence for dendrodendritic synapses gives a new meaning to that acute observation by Ramón y Cajal. Later I return to the possible functional analogies between granule cells in the bulb and amacrine cells in the retina. A note about terminology: although "amacrine" (a, neg. + makros, long + inos, fiber; having no long processes: the American Illustrated Medical Dictionary, 1951) may be an etymologically appropriate term for both these cell types, I retain the term "granule" in this report because of its established use for these cells in the olfactory bulb.

The other neuronal types in the bulb include, briefly, tufted cells that are scattered throughout the external plexiform layer. Their dendritic patterns are similar to those of mitral cells, but their axonal projections are different and, in fact, a matter of debate. Around the glomeruli are numerous cells with short axons (not shown in Figure 1) which connect neighboring glomeruli. Finally, there are some short-axon cells scattered in the granule cell layer. Although I concentrate on the mitral and granule cells in this report, our microelectrode studies have yielded information on the functional connections of these other cell types, too, and they are included in the schema for intrabulbar pathways in Figure 7.

Excitation and inhibition of mitral cells

A shock to the lateral olfactory tract sets up a synchronous volley of impulses in the mitral-cell axons. The impulses travel antidromically in the axons into the olfactory bulb, where they invade the mitral cells. The mitral cells in turn activate other cells in the bulb to which they are synaptically connected. This activity generates extracellular current around the activated cells, mitral and others, and a microelectrode inserted into the bulb records the potential changes caused by the summed current flow generated by the populations of active cells.

A typical sequence of recordings from the surface to the depth of an olfactory bulb is shown on the right in Figure 2. On the left is a tracing of a histological section containing the electrode path over which these records were obtained. The records are shown connected to the depths at which they were recorded. Each trace begins with a short base line, followed by a gap indicating the artifact of the tract shock, and then a sequence of positive- or negative-potential deflections. The analysis of these summed potential patterns is described by Rall. Here it may be noted that the patterns are distinctive for different layers of the bulb and can therefore be used at the time of recording of unit potentials to

Positivity of pipette recording tip is upward in this recording and in those that follow.

find the depth of the micropipette tip (Phillips et al., 1961; 1963). Recordings similar to those in Figure 2 have been reported by Baumgarten et al. (1962) and Ochi (1963).

The first question of physiological interest is how impulses are generated in the mitral cell. Figure 3 shows micropipette recordings from a unit at the layer of mitralcell bodies, as judged by the potential wave pattern. A single shock to the lateral olfactory tract elicited a single, all-ornothing, positive-negative spike in successive trials. The recording tip was extracellular; the spike is of the order of 25 millivolts peak-to-peak, and is therefore a so-called "giant spike," like those that have been recorded from many other neurons in the CNS (cf. Granit and Phillips, 1956; Phillips, 1959). Record A in Figure 3 shows direct antidromic invasion at a fixed latency of about 1.0 millisecond and permits this unit to be positively identified as a mitral cell.

In Figure 3B a single shock to an olfactory nerve bundle also elicited a single spike. The latency was much longer because of the slow conduction velocity of the unmyelinated olfactory nerves, and the latency was variable because activation was across the synapse in the glomerulus, and the volley was near threshold. With stronger shocks (C and D), the latency decreased and became less variable. There was a prominent hesitation on the spike during antidromic invasion and during threshold orthodromic activation; this was reduced by the stronger volleys, and the spike duration also decreased. It appears that there is an A-B sequence of impulse generation, from, presumably, axon hillock to cell body, and that there is tighter coupling with increasing synaptic depolarization. Thus, the mitral cell generates spikes in a sequence like that in motor neurons (cf. Fuortes et al., 1957; Eccles, 1957) and many other neurons, despite the particular morphology of its dendrites. That the spikes in mitral cells are brief is important in regard to the recurrent input from the granule cells, as is discussed below.

Prolonged "dendritic" spikes (Tasaki et al., 1954) were never seen, except during injury discharges.

Do these volleys produce any other effect on the excitability of the mitral cell? This was studied by testing the ability of a mitral cell to respond with an antidromic impulse after a conditioning antidromic or orthodromic volley. Some mitral cells could respond at any time except during the first few milliseconds, corresponding to the absolute refractory period; in such cases, the refractory period was similar after either an antidromic or an orthodromic impulse.

In many mitral cells, however, there was a long-lasting blockage of impulse generation, as illustrated in Figure 4.

FIGURE 4 Relation between strength of conditioning shocks to lateral olfactory tract (ordinate) and duration of blockage of impulse generation (abscissa) in two mitral cells. Axon thresholds: closed bars, 330 microamperes; open bars, 750 microamperes. Bars indicate periods of blocking of testing antidromic spikes. (From Phillips et al., 1963.)

The closed bars indicate the periods during which antidromic impulse invasion in one mitral cell was blocked after a conditioning antidromic volley. It can be seen that the onset, duration, and recovery of blockage were graded with the strength of the conditioning shock. All the conditioning shocks, except the strongest (340 microamperes), were below threshold for the axon of this mitral cell. It may be presumed that the shocks were above threshold for other mitral axons in the lateral olfactory tract, and that connections from these other mitral cells caused the blockage of impulse generation in the cell. Therefore, the blockage can be ascribed to true inhibition, as distinct from depression following a spike in this cell. When a conditioning spike did occur (340 microamperes in Figure 4), the blockage lasted much longer, and it could be shown that in many cells the duration was graded with the strength of the suprathreshold conditioning shocks. In such cases, the blockage appears to be due to a combination of refractoriness after the spike, self-inhibition of the cell, and inhibition caused by other mitral cells.

The latency of onset of the inhibition became shorter as the shocks were made stronger, presumably by activation of more mitral axons in the tract. In Figure 4 (closed bars)

the minimum latency with the shock just subthreshold was 4.8 milliseconds; with the shock just suprathreshold the refractoriness in the aftermath of the spike merged with the period expected for inhibition. In some mitral cells these two periods were not continuous, and a second antidromic spike could be interjected between the two periods. Detailed study showed that the minimum delay for the onset of the inhibition was about 3.0 milliseconds, with a range of from 3 to 5 milliseconds in our population of mitral cells. In some cells the inhibition had a very long latency, up to tens of milliseconds; in other cells it could be elicited only by repetitive stimulation of the tract. All these characteristics suggest that the inhibition is mediated by a pathway that contains more than one synaptic relay. The maximum duration of the inhibition was of the order of several hundred milliseconds.

Closely similar results were obtained when an antidromic impulse was interjected in the aftermath of a conditioning shock to the olfactory nerves. In some cells the antidromic impulse was blocked only in the brief refractory period after the orthodromic impulse. In many cells, however, blockage was long-lasting and resembled the inhibition after a tract shock. Thus, it occurred after a subthreshold conditioning shock; its timing of onset and recovery was graded with conditioning shock strength; the minimum latency of onset was several milliseconds after the arrival of the orthodromic volley in the bulb. It was concluded that an orthodromic volley activated the same pathways within the bulb for mitral inhibition, in roughly the same temporal sequence, as did an antidromic volley. This similarity extended to the finding that an antidromic spike could also be interjected between the periods of refractoriness and inhibition after a spike that was elicited orthodromically. The results from orthodromic conditioning were therefore important in establishing that mitral-cell inhibition could be produced by activation of natural orthodromic pathways.

The analysis of mitral-cell inhibition has been carried out largely with extracellular unit recordings, because intracellular recordings are exceedingly difficult to obtain from the relatively small mitral cell and, when they are obtained, the membrane potential is low and deteriorates rapidly. The few successful recordings by Yamamoto et al (1963) and ourselves (Phillips et al., 1963), recently confirmed by Nicoll (1969), show clearly, as in Figure 5A, that a hyperpolarization of the mitral-cell membrane occurs after a volley in the tract or olfactory nerves, and that the timing of onset and recovery, and grading with shock strength, are similar to those of the spike inhibition recorded extracellularly. In the recording in Figure 5A, hyperpolarization began at about a 5-millisecond latency and lasted for about 30 milliseconds; the peak hyperpolarization was about 7 millivolts, which is not very meaningful because the resting potential was low and deteriorating. The recordings per-

FIGURE 5 A. Intracellular recording from a mitral cell, showing hyperpolarization following lateral olfactory tract shock. Vertical bar indicates 10 millivolts. Extracellular recording at same (B) and higher amplification (C) after loss of cell. Time in 2-millisecond intervals.

mit, however, the tentative conclusion that this is an inhibitory postsynaptic potential (IPSP), and we presume, in the absence of any other evidence, that it arises from ionicconductance changes in the mitral-cell membrane similar to those responsible for IPSPs in motor neurons and other CNS neurons (cf. Eccles, 1964).

Neuronal systems in the bulb

The relatively long latency of the mitral-cell inhibition raises the likelihood of an interneuron in the inhibitory pathway. It will be recalled from the description of bulbar anatomy that the secondary dendrites of the mitral cells are intermingled with the radial processes of the granule (amacrine) cells in the external plexiform layer. We therefore suggested, on the basis of our unitary studies (Phillips et al., 1963; Shepherd, 1963b), that the granule cell is the interneuron which mediates inhibition of the mitral cells, through inhibitory synapses on the mitral-cell secondary dendrites.

What, then, is the pathway for activation of the granule cells? One possibility is that deep collaterals from mitral axons have excitatory synapses on deep dendrites of granule cells; the activated granule cell would then inhibit the mitral cells. This would be analogous to the pathway for Renshaw inhibition in spinal motor neurons (Eccles et al., 1954). Evidence relating to such a pathway was gained from unit recordings in the granule layers. As shown in Figure 6A, a threshold shock to the tract was followed by the brief field potential associated with mitral-body invasion and then a single spike. With stronger shocks—two, three, and four times threshold—there was a repetitive discharge of two, three, and four spikes. In successive trials at $\times 1$ threshold, the spike latency varied somewhat; with increasing shock strength the latency of the first spike decreased. These are properties of synaptic activation, and are in contrast to antidromic spikes in mitral cells, which always had fixed latencies.

It is of interest that a different type of repetitive response is found in units situated superficially, near the olfactory glomeruli. The unit in Figure 6B responded to an olfactory nerve volley at threshold with a train of seven spikes, lasting about 30 milliseconds. The shock to the nerves was increased from (a) to (e); at three times threshold (c) the discharge increased only from seven to nine spikes, with the same train duration, and at 12 times threshold (e) the discharge still consisted of nine spikes, and the train duration was actually shorter. It can be seen that the spikes in the middle of the train were markedly reduced in amplitude. This appears to be the kind of "inactivation" found in Purkinje cells (Granit and Phillips, 1956) and hippocampal pyramidal cells (Kandel and Spencer, 1961) when they are excessively depolarized. Intracellular recordings by Yamamoto et al. (1963) have revealed the appropriate depolarizing response of cells in this region to olfactory nerve volleys. An interesting feature of these cells is that the impulse discharge is a very stereotyped affair, independent to a certain extent of the amount of depolarization impressed on the cell by the afferent volley.

A summary of the relation between the physiological findings and the anatomy of the bulb is provided by the schematic diagram in Figure 7. The anatomy is based on the studies of Ramón y Cajal (1911), as in Figure 1; the excitatory (E) and inhibitory (I) synaptic connections are based primarily on the results of our unit recordings.

To summarize briefly, an antidromic impulse in one mitral axon invades the cell and subsequently causes inhibition of that cell and neighboring cells through inhibitory synapses from the granule cell onto the mitral secondary dendrites. The repetitive discharges of units in the granule layer seemed to provide evidence for activation of the granule cells through the deep collaterals of the mitral axons, in analogy with the Renshaw pathway from motoneuron axon collaterals to interneurons in the spinal cord (Eccles et al., 1954). We were puzzled, however, at the time (Phillips et al., 1963; Shepherd, 1963b) by the fact that the granule layer units were found only infrequently, in contrast to the widespread nature of the mitral inhibition and the large numbers of granule cells. Furthermore, the repeti-

FIGURE 6 Two types of repetitive response found in bulbar units. A. Unit recorded in granule layer; synaptic responses to tract volley at threshold (\times 1) and at two, three, and four times threshold. Time in milliseconds; vertical bar, 2 millivolts. (From Shepherd, 1963b.) B. Unit recorded in outer zone of external plexiform layer; synaptic responses to olfactory nerve volley at threshold (a), and at two (b), three (c), six (d) and 12 (e) times threshold. Time, 10 milliseconds; vertical bar, 5 millivolts.

tive discharges were very brief, so that one had to postulate some special property, such as prolonged transmitter action, to account for the prolonged mitral inhibition.

Recent work has shown (Rall et al., 1966; Rall and Shepherd, 1968) that there is another pathway for activating the granule cells, through the same mitral dendrites that are then inhibited. This new type of functional pathway was suggested by the analysis, described by Rall in this volume, of the extracellular field potentials in the bulb (cf. Figure 2). The synaptic connections that would provide for such a pathway have been demonstrated in several electron-microscope studies (Hirata, 1964; Andres, 1965; Rall et al., 1966). The electron micrograph in Figure 8, from the work of

Renshaw type of pathway from mitral-axon collaterals would be basically the same: activation of the granule cell followed by inhibition of the mitral cell (cf. Figure 9).

It remains to be determined whether the repetitively firing units in the granule layer are, in fact, granule cells, or are short-axon cells playing a similar or perhaps different functional role. In contrast, units in the external plexiform layer respond to a tract volley with a single variable latency spike. This type of response suggests synaptic excitation, most probably via the recurrent collaterals of the mitral cells, followed by synaptic inhibition via the granule cells. Tract volleys rarely activate glomerular cells, but sometimes cause weak inhibition, suggesting that granule cells may

FIGURE 7 Schematic diagram of olfactory bulb pathways and connections between different neuron types, based on Ramón y Cajal (1911) and recent findings. Presumed excitatory and inhibitory connections are labeled E and I, respectively. Small arrows indicate direction of activity. Histological layers of the bulb are indicated at left. For explanation, see text. (Modified from Shepherd, 1963b.)

FIGURE 8 Characteristic synapses between mitral-cell dendrite (m) and gemmule of a granule-cell dendrite (g). There are two synaptic contacts with opposite polarities (determined by cluster of vesicles), as indicated by the arrows. These synapses provide for mitral-to-granule excitation and

granule-to-mitral inhibition (see text). In mitral-to-granule synapse, (f) identifies dense filamentous material attached to postsynaptic membrane. Lead citrate. ×100,000 (From Rall et al., 1966.)

Reese and Brightman (Rall et al., 1966), shows clearly the side-by-side synapses of opposite orientation which would provide for the sequence of mitral-to-granule excitation followed by granule-to-mitral inhibition that is postulated by the physiological analysis. The synapses connect mitral secondary dendrites with the peripheral dendrites of the granule cells, and we have therefore termed this a *dendro-dendritic synaptic pathway for recurrent inhibition* of the mitral cells. The effect of either the dendrodendritic pathway or a

also have inhibitory synapses on them. Thus, the unit recordings lead to the concept of the granule cell as the common inhibitory interneuron in the olfactory bulb, mediating inhibition of the tufted and glomerular cells as well as of the mitral cells.

To turn to the pathways for orthodromic activation—a volley in the olfactory nerves synaptically excites all the cells connected to the glomeruli. The glomerular cell tends to respond with repetitive firing, the tufted and mitral cells with a single impulse followed by inhibition. An important point is that the inhibition is brought about over the same pathways through the granule cells as in the antidromic case. The synaptic actions of glomerular and tufted cells are still a matter for conjecture. The glomerular cell has horizontal connections which could provide for a spread of activity to mitral-cell dendrites in neighboring glomeruli; this spread would be opposed by inhibition from the granule cells. Thus, inhibition from the granule cell could be pitted against excitation from the afferent nerves and glomerular cells, thereby providing a mechanism for modulating excitability at the level of the afferent input to the mitral dendritic tuft in the glomerulus. The tufted-cell axon, according to Ramón y Cajal, gives off many collaterals in the internal plexiform layer just below the mitralcell bodies. These could provide for synaptic activation of granule cells, with the consequent recurrent inhibition, or they could provide for a synaptic modulation of granulecell excitability, to control the amount of inhibition delivered by the granule cells when activated by the mitral cells. The diagram in Figure 7 emphasizes that the bulb actually contains several neuronal systems related to the glomerular, tufted, and mitral cells. To a degree, these systems operate independently; to a degree, they compete for control of the excitability of the mitral and granule cells.

Functional implications of neuronal interactions in the bulb

I suggested in the introduction that the bulb could be viewed as a simple cortical system. The test of such a view is the extent to which the experimental results have implications beyond the bulb. Specifically, do the neuronal interactions as summarized in Figure 7 have relevance only to the peculiar demands of discriminating olfactory stimuli, or do they, in addition, provide insights into the functional organization of other "cortical" regions? The results from the unit studies that I have described, and from the theoretical studies of summed extracellular potentials that Rall describes, do appear to have functional implications of general interest. These may be summarized as follows; some of the points are discussed here, and some are treated in more detail by Rall in his chapter.

1. KEY INTEGRATIVE FUNCTION FOR AXONLESS CELL The unit analysis, potential wave analysis, and electronmicroscope studies provide clear evidence that a cell that lacks an axon can, nonetheless, play a key role in nervous integration. In the granule cell, this role appears to be an inhibitory one. The dendrodendritic synapses between granule and mitral-cell dendrites provide for close control of the mitral-cell output. It appears that the granule cell also inhibits tufted and glomerular cells; thus, an interneuron may have inhibitory synapses on more than one neuron type.

2. THE DEFINITION OF DENDRITE The finding of synaptic connections between the dendrites of mitral and granule cells raises questions about our present terminology for the different parts of a neuron. The neuron doctrine has never been satisfactory in this regard; the problem has been well reviewed by Bodian (1962), who offered the following definitions consistent, at the time, with both morphological and physiological evidence. Dendrites, he suggested, are those processes that "receive synaptic endings of other neurons"; axons "conduct nervous impulses away from the dendrites," and axon telodendria (terminals) provide for "synaptic transmission to the dendrites of other neurons."

These definitions, as they stand, must now be modified to account for the findings in the olfactory bulb. The peripheral process of the granule cell not only receives synaptic excitation from mitral cells, but also provides synaptic inhibition to the mitral cells. It might be argued that, because the granule cell lacks a morphologically identifiable axon, the peripheral dendritic processes are functionally analogous to axonal telodendria. Such an explanation cannot apply to the mitral cell, however, which clearly does have an axon; the mitral-cell dendrites are presynaptic as well as postsynaptic to the peripheral dendrites of the granule cells. Thus, both the mitral and granule dendrites perform functions as synaptic effectors as well as synaptic receptors. In addition, the effector function of one kind of dendrite (mitral) is excitatory, and the other kind (granule) is inhibitory.

Several suggestions can be offered toward resolving this terminological dilemma. One is that the criteria of Bodian may still be valid if they are not exclusive, that is, if dendrites may transmit as well as receive, and axonal terminals may receive as well as transmit. The latter concept has already been introduced by work on presynaptic inhibition in peripheral and central neurons (cf. Eccles, 1964). The designation of a neuronal process as a "dendrite" might then be based on its pre-axonal position in the overall, normal flow of activity in a neuron, rather than on an exclusively receptor function. It would, of course, be convenient if one could identify a dendrite by specific ultrastructural criteria, or by a functional property such as the generating of graded potentials in contradistinction to propagating impulses, as in axons. Evidence for such criteria that would apply to all vertebrate neurons, however, is insufficient at present.

If a process is to be identified as a dendrite on the basis of its pre-axonal position, how then to identify the peripheral process of the granule cell, which lacks a morphologically identifiable axon? Here one can begin with the commonsense observations that what is not axon must be dendrite, that with Golgi stains the peripheral process can be seen to have branches and spines which resemble those of the apical dendrites of pyramidal cells in neocortex and hippocampus, and that a close resemblance of these dendrites is also found at the ultrastructural level (cf. Rall et al., 1966; Price, 1968). With regard to the pre-axonal position of this process, it may be suggested that it must be seen in the context of the synaptic connections with the mitral-cell dendrites. In this context, the peripheral process of the granule cell is a dendrite with respect to the axon of the mitral cell.

This view can be spelled out in more detail by reference to the diagram in Figure 10. To anticipate the discussion (point 7, below), this diagram shows the similar positions of granule and amacrine cells in the organization of the bulb and retina. In the normal flow of activity through the bulb, the granule cell, as do the mitral-cell dendrites, provides for the spread of activity (excitatory or inhibitory) prior to integration at the mitral-axon hillock and conversion there into the frequency-coded impulse discharge of the mitral axon. Seen in this context, the granule cell is "dendritic" vis-à-vis the mitral-axon hillock in both its receptor and its effector synaptic functions. Similar considerations apply to the retinal amacrine cell. In addition, the same argument can be applied to the bipolar cells in the retina. Figure 10 shows that the bipolar cell is analogous to the primary dendrite of the mitral cell, in that both of these processes pass on activity from the receptor level to the axon hillock of the output neuron. The entire bipolar cell functions as a dendrite with respect to the axon hillock site (on the ganglion cell) where its activity is integrated with that of the horizontal (amacrine) pathways.

It may be noted that this extension of the basis for neuron terminology to include the functional context is in line with Bodian's (1962) statement that "the basic role of the neuron is that of its relation to other cells." This view may now be seen to be completely general, in the sense that instances may be found in which any of the conventionally designated parts of a neuron (dendrites, soma, axons, telodendria) may have receptive (postsynaptic) or transmissive (presynaptic) sites.

3. DIFFERENT TYPES OF DENDRITE In Golgi and electronmicrograph sections the mitral dendrites are smooth, as are motor neuronal dendrites, whereas the granule dendrites are invested with spines, as are apical dendrites of pyramidal cells. The two types of dendrite stain differentially in Bouin's fixed material. Are these two basic types of dendrite, and, if so, what is their functional significance? Is it related to their excitatory and inhibitory synaptic connections? Or is it related to rapid impulse generation in the smooth-dendrite cell and slow, partial, or prolonged regenerative activity in the spinous-dendrite cell? In this view the smooth-dendrite cell might provide for instantaneous integration of synaptic inputs, while the spinous-dendrite cell might provide for long-term integration and possibly retention of information.

4. Full Action Potential not Required for Den-DRITIC FUNCTION Neither mitral nor granule dendrites appear to need a propagating action potential to carry out their different functional roles. In the mitral cell, the primary dendrite provides for coupling between the synaptic input in the glomerulus and impulse generation in the mitral-axon hillock, and the secondary dendrite provides coupling between the hillock and the sites of dendrodendritic synaptic action. The electrotonic lengths of both types of dendrite appear to be adequate for effective spread of impulse depolarization, even if the dendritic membrane were passive. There is reason to belive that regenerative activity in the granule cell may be partial or decrementing; spread of depolarization to neighboring gemmules could occur because of the relatively short distances in the granule dendritic tree. It is clear, however, that the granule-cell response to the mitral dendritic input does not involve the entire granule cell. Regenerative activity, if present, must be largely restricted to the peripheral dendritic branches in the external plexiform layer.

5. GENERALIZES RECURRENT INHIBITION Figure 9 shows a comparison between the new dendrodendritic pathway for recurrent inhibition and the classical Renshaw pathway through an axon collateral. In both diagrams it is assumed

FIGURE 9 Two types of pathway for recurrent inhibition. Left: Classical Renshaw inhibitory pathway (Eccles et al., 1964) from axon collateral through interneuron. Right: New dendrodendritic inhibitory pathway (Rall et al., 1966; Rall and Shepherd, 1968) from dendrite through interneuron. Direction of normal flow of activity is shown by arrows. Excitatory and inhibitory synapses are labeled E and I, respectively. Site of impulse generation at axon hillock is indicated by shading.

that a synaptic input from above generates an impulse in the hillock region. In Renshaw inhibition, the impulse on the axonal side of the hillock, through synaptic excitation of the interneuron, delivers synaptic inhibition to the same cell and to neighboring cells. In dendrodendritic inhibition, the impulse spreading back into the dendrites excites the interneuron synaptically, which, in turn, inhibits the same cell or neighboring cells.

We have suggested that the term "recurrent inhibition" should be generalized to cover each type of pathway, because both provide for inhibitory feedback to the same or neighboring cells. As the Renshaw circuit loops back from axon to dendrite, it can be viewed as "trans-hillock." In comparison, the dendrodendritic circuit is seen to be "prehillock." Further work is required on the functional significance of the inhibitory control that is possible over these pathways in different regions of the CNS. It is of interest that both pathways appear to be present in the granule cell.

It may be noted that the pre-hillock pathway appears to require a "fractionation" of the dendritic field (cf. Sprague, 1958), so that the initial synaptic excitation of the cell does not "shunt out" the dendrodendritic synapses. The synapses are activated by the impulse spreading from the hillock, and, as mentioned above, the impulse is brief, so that shunting between the synapses does not occur.

6. RHYTHMIC POTENTIALS The electrical activity of the bulb is characterized by potential oscillations ("EEG waves") of large amplitude. We have noted that the dendrodendritic synaptic interactions are well suited for the development of such rhythmic activity. The mechanism can be understood with reference to Figure 10 (bulb). Impulse discharge in mitral cells results in synaptic excitation of many granule cells; these granule cells then deliver graded inhibition to many mitral cells. This inhibition cuts off the source of synaptic excitatory input to the granule cells. As the granule-cell activity subsides, the amount of inhibition delivered to the mitral cells is reduced, which permits the mitral cells to respond again to the excitatory input from the glomeruli. In this way a sustained excitatory input to the mitral cells would be converted into a rhythmic sequence of impulse followed by inhibition, locked in timing to a rhythmic activation of the granule cell pool.

7. MECHANISM FOR SELF AND LATERAL INHIBITION Itappears probable that, during natural activity, a mitral cell exerts on its neighbors the kind of lateral inhibition that is a common feature of many sensory systems. This mechanism might operate in the bulb to sharpen contrast, or it might be related to the adaptation that is such a marked feature of olfactory sensations. The lateral spread of the inhibition would be promoted by the long lengths of the mitral secondary dendrites, the numerous reciprocal synapses on granule dendrites, and the spread of depolarization in the excited granule dendrites. Within this framework, the inhibition may have a selective action because of the local character of the feedback. This kind of selective action is not possible with the Renshaw pathway, because the impulse in the axon of the interneuron presumably invades all the axonal terminals (cf. Figure 9).

8. SIMILARITIES IN ORGANIZATION OF OLFACTORY BULB AND RETINA Because the granule cell and the retinal amacrine cell are the two outstanding examples in the CNS of neurons without axons, it is of interest to see what further comparisons can be made between the two. These lead to the recognition of some basic similarities in the organization of the bulb and the retina, which are discussed in relation to the two schematic diagrams in Figure 10.

FIGURE 10 Diagram showing similarities in organization of olfactory bulb and retina. Neurons are shown schematically; note especially the compression of receptor and granule cells in bulb, to emphasize their primary functional connections. Normal flow of activity is indicated by arrows. For presumed synaptic actions and full discussion, see text.

The bulb appears to be organized along the following principles. There are input cells (the olfactory receptors) and output neurons (the mitral cells). There are vertical pathways for direct activation of the bulbar output neurons and horizontal pathways for integrating the vertical paths. The horizontal connections are organized into two tiers, the first apparently for controlling the bulbar input, the second for controlling the bulbar output. It can be seen that the granule cells are at the level of output control; this control is carried by the reciprocal synaptic connections with mitral secondary dendrites, which can be viewed as sidearms on the vertical pathways. The control exerted by the granule cells on the mitral-cell output appears to be exclusively inhibitory. The synaptic actions of the glomerular cells, at the input level, are not known. Further modification of the mitral-cell output would arise from activity in pathways related to tufted cells, mitral-axon collaterals, and shortaxon cells (cf. Figure 7).

The diagram of the retina on the right of Figure 10 is based on the Golgi studies of Ramón y Cajal (1911) and the recent electron-microscope studies of Dowling and Boycott (1966). It shows that the retina appears to be organized on principles similar to those of the olfactory bulb. There are input cells (the visual receptors) and output neurons (the ganglion cells). There are vertical pathways from receptors through bipolar cells to ganglion cells, and horizontal pathways connecting the vertical paths. The horizontal connections are also organized in two distinct tiers, the first related to control of receptor input to the bipolar cells, and the second related to control of retinal output by the ganglion cells. It can be seen that the amacrine cell, as is the granule cell in the bulb, is at the level of output control; this control is through connection with the vertical pathway by reciprocal synapses (Kidd, 1962; Dowling and Boycott, 1966) between the amacrine cells and the bipolar terminals. In the primate retina, the bipolar terminals form synapses with both ganglion cells and amacrine cells, as depicted in the diagram. In the more complex retina of the frog, one or more amacrine processes are interposed between the bipolar terminals and the ganglion cells. This does not alter the basic plan shown in the diagram, except for the removal of most of the direct bipolar-to-ganglion synapses, and the substitution of amacrine-to-amacrine relays where necessary.

On morphological grounds, therefore, granule cells and amacrine cells exhibit striking similarities. Both lack an axon, and both take part in reciprocal synaptic connections. The granule cell is both postsynaptic and presynaptic to the mitral cells, and the amacrine cell is both postsynaptic and presynaptic to the bipolar cells. On the basis of these similarities we suggested (Rall et al., 1966; Rall and Shepherd, 1968) that the retinal amacrine cells might provide a type of dendrodendritic inhibitory pathway similar to that demonstrated for the granule cell in the bulb. A further similarity, brought out by the diagrams in Figure 10, is that the inhibition by the amacrine cells would also be at the level of output control, by monitoring the bipolar input to the ganglion cells.

This hypothesis must, of course, be tested by work on the retina. Recent studies by Werblin and Dowling (1969), A. Kaneko (personal communication), and D. A. Baylor (personal communication), combining unit recordings and histological identification, are therefore of great interest. These workers are in general agreement that, in the sequence from receptors to ganglion cells, center-surround antagonism is first found in bipolar cells. This is consistent with the hypothesis that amacrine cells are inhibitory to bipolar terminals, although it does not rule out an inhibitory input from horizontal cells to bipolars. Inhibition from amacrine cells might also be related to adaptation or to directional sensitivity; these possibilities are under investigation (Barlow and Levick, 1965; Werblin and Dowling, 1969).

In view of the similarities in the organization of retina and bulb, work on the retina takes on added significance for the bulb. Little is known of the bulbar mechanisms underlying olfactory discrimination, mainly because the odorous stimulus cannot be adequately controlled. By contrast, precise control of light stimuli has enabled much to be learned about the functional properties of the retina. If the retina and bulb are similar in their organization, the kinds of information and the ways in which the information is handled in the bulb might be similar to those in the retina. As an example, lateral inhibition in the retina provides a mechanism for heightening contrast at a light-dark boundary. In view of the pathway for lateral inhibition demonstrated in the bulb, does this imply a mechanism to heighten contrast at heretofore unknown "boundaries" in the olfactory input to the bulb? As another example, the analytical capacity of ganglion cells of different species appears to be related to the complexity of the synaptic connections between bipolar, amacrine, and ganglion cells (cf. Michael, 1969). These synapses provide the ganglion cells with additional degrees of freedom from vertical and horizontal control, in contrast to the direct control in the case of the mitral cell. Does this imply that the mitral cell is relatively limited in the amount of analysis that it can carry out on the olfactory input? Such questions may give insight into the nature of the olfactory stimulus and suggest new experimental approaches to the difficult problem of olfactory discrimination.

Summary

The mammalian olfactory bulb can be viewed as a simple cortical system. Because of the separation of afferent and efferent pathways, selective orthodromic and antidromic activation of the neuron populations within the bulb can be achieved. Unit recordings have permitted analysis of spike generation in mitral cells and of pathways for synaptic excitation and inhibition of other types of neurons. Biophysical reconstruction of field potentials evoked in the bulb led to the postulation of dendrodendritic synaptic interactions between mitral and granule cells. Electronmicrographs have revealed the postulated synapses between mitral and granule-cell dendrites. These synapses provide a pathway for recurrent inhibition of the mitral cells; we have suggested that the term "recurrent inhibition" be generalized to cover this dendrodendritic synaptic pathway as well as the classical Renshaw pathway through an axon collateral. Although it lacks an axon, the granule cell nevertheless plays a key integrative role by virtue of its inhibitory control of mitral cells.

The results thus far in the olfactory bulb have implications of general interest to neurobiologists, particularly with regard to the nature of recurrent inhibition, the integrative properties of neuronal dendrites, and the organization of the retina and of other cortical structures. An important aspect of this work has been the extent to which several methodologies and techniques--histological, ultrastructural, physiological, biophysical-have been brought to bear on single problems, e.g., the synaptic pathway for recurrent inhibition of mitral cells. This may be taken to reflect the advantages of working on a simple or "reduced" cortical system like the bulb. As Rall shows in his chapter in this volume, the simple features of the bulb have also permitted realistic biophysical models to be constructed for both the mitral and granule-cell populations. Thus far our interest has been in gaining understanding of the functional organization of the neuronal populations within the bulb; it is hoped that this will lay a foundation for future work on the neuronal mechanisms underlying the sensory discrimination of odors.

Acknowledgments

A number of my colleagues have kindly read the manuscript and given valuable advice. Among them I am particularly indebted to Drs. W. Rall, C. G. Phillips, T. S. Reese, D. Ottoson, C. M. Michael, and D. Bodian.

50 Dendritic Neuron Theory and Dendrodendritic Synapses in a Simple Cortical System

WILFRID RALL

GORDON SHEPHERD, in his presentation, focused attention on the experimental evidence that provided the basis for our theoretical work on the olfactory bulb. He also discussed several wider implications of these experimental and theoretical results. Here, I wish to focus attention on theoretical aspects of this study. First, I describe a general theoretical approach that can be applied to different neurons or neuron populations and to different parts of nervous systems. Then I consider the specific application to the olfactory bulb and focus attention on particular points that proved to be most important for our interpretations. A comprehensive report of our analysis, results, and interpretations has already been published (Rall and Shepherd, 1968).

Theoretical Method

Briefly, the theoretical method combines several mathematical models. One group of models is based on the biophysical models of nerve membrane; the simplest represents passive nerve membrane; another provides for synaptic excitation and inhibition; still others provide for the generation and propagation of active nerve impulses. Another group of models is concerned with the abstraction and simplification of dendritic branching. Still another group is based on considerations of geometric symmetry in a cortical arrangement of neurons, especially when these neurons are activated synchronously. Such mathematical models were combined in a computer program, which was then used to predict spatiotemporal distributions of extracellular potential; these distributions were compared with those previously recorded experimentally in the olfactory bulb.

DENDRITIC BRANCHING That neuronal dendritic branching can be very extensive has been well known for many years and has been widely illustrated. The details of such branching often appear to be impossibly complicated. The purpose of Figure 1 is to illustrate how dendritic branching can be abstracted, idealized, and simplified. The dendritic tree (Figure 1A) preserves branching but idealizes it to a symmetric branching pattern; the equivalent cylinder (Figure 1B) and the two chains of compartments (Figure 1C and D) reduce the spatial aspect of the dendritic tree to a single dimension, namely, the distance from the neuronal soma out into the dendritic tree. For those problems that involve either disturbances that spread from the neuronal soma outward into all of the branches or those that arise at corresponding locations in all members of a set of corresponding branches, consideration of the symmetry provides a justification for such simplification to a single space dimension.

It has been demonstrated mathematically (Rall, 1962a) that there is a class of dendritic trees which can be transformed into an equivalent cylinder. Briefly, this demonstration involved a consideration of the partial differential equation (cable equation) for spatiotemporal distributions of

WILFRID RALL Mathematical Research Branch, National Institute of Arthritis and Metabolic Diseases, Bethesda, Maryland

membrane potential in passive membrane cylinders, together with a consideration of the boundary conditions to be satisfied at every point of branching and of branch termination. In addition to providing a constraint upon the relative diameters of parent and daughter branches at every branch point, this analysis demonstrated the advantage of expressing the actual length, ℓ , of each dendritic branch, as an *electrotonic length*, L. This is defined as ℓ/λ , where λ , known as the *characteristic length*, is a basic parameter in the original cable equation. The value of λ depends on the resistivities of the materials and on the square root of the diameter of each membrane cylinder. The equivalent cylinder (Figure 1B) is characterized by a single value of λ , whereas the dendritic tree (Figure 1A) is characterized by many different values of λ for the different values of branch diameter.

FIGURE 1 Schematic diagrams of simplified models of a neuron. A. Dendritic tree with an idealized, symmetrical, branching pattern; its trunk arises from a portion of the neuronal soma. B. Membrane cylinder that can be regarded as equivalent (electrotonically) to the entire dendritic tree (including its portion of the soma) when certain conditions are satisfied (Rall, 1962a). C. Chain of five equal compartments. Each compartment corresponds to a lumping of one-fifth of the length of the cylinder (B), or one-fifth of the surface area of the dendritic tree (A), as indicated by the dashed lines in (A). D. Chain of 10 equal compartments. Each compartment corresponds to a lumping of one-tenth of the equivalent membrane cylinder (B); compartment 1 represents the soma, and compartments 2 through 10 represent successive increments of electrotonic distance from the soma out to the dendritic terminals (Rall, 1964).

ELECTROTONIC LENGTH For the equivalent cylinder, the electrotonic length is a simple concept; its importance results from the fact that this L also represents the electrotonic length of the entire dendritic tree (Figure 1A), including its portion of the neuronal soma. For some neurons it is useful to combine all dendritic trees and to characterize the entire soma-dendritic complex as an equivalent cylinder with some particular value of L. For other neurons, and for some patterns of neuronal activation, it is necessary to consider several equivalent cylinders coupled to a common soma, and in some cases to consider also subdivisions of dendritic trees. Our theoretical computations of activity in the olfactory bulb required us to assume values of L for mitral-cell dendrites and for granule cells. For motoneurons of cat spinal cord, the significance of the value of L for an understanding of synaptic potentials and their properties has recently been demonstrated in some detail (Rall et al., 1967). Also, a theoretical basis for estimating the value of L from an analysis of electrophysiological transients has recently been provided (Rall, 1969); this approach may prove to be useful with neurons of many different types.

COMPARTMENTAL MODELS As indicated by Figure 1C and 1D, a chain of equal compartments can be used to approximate the equivalent cylinder. Each compartment represents a lumping of dendritic membrane. The essential, simplifying assumption is that nonuniformity of membrane potential is neglected within each compartmental region; nonuniformity is represented only by differences between compartmental regions. The chain of 10 compartments (Figure 1D) represents the one dimension, electrotonic distance, extending from the soma (compartment 1) outward into all the dendritic branches in nine lumped steps that correspond to equal increments of electrotonic distance and of membrane surface area.

An advantage of compartmental models is that they are not restricted to the special case of the equivalent cylinder. Compartments of different sizes are used whenever needed to represent significant departures from the idealized equivalent cylinder. Also, branching systems of compartments are used whenever it is necessary to distinguish among several dendritic trees of a single neuron, or among several divisions of a single dendritic tree. Furthermore, different synaptic inputs and different membrane properties can be specified for different compartments when required.

The mathematical model implied by such a compartmental diagram is a system of ordinary differential equations (see Rall, 1964, for details and references). These equations are linear and of first order for those compartments in which active nerve membrane properties are not present. The system of equations becomes complicated by additional nonlinear differential equations when one or more compartments must exhibit active membrane properties.

MEMBRANE MODELS The diagram in Figure 2 indicates the lumped membrane parameters for a single compartment. This equivalent electrical circuit is related to the papers of Hodgkin and Katz (1949), Fatt and Katz (1951 and 1953), Hodgkin and Huxley (1952), and Coombs et al. (1955); see also Cole (1968). In a completely passive membrane, the excitatory and inhibitory conductances, G8 and G_i, are both zero, and there remains the resting conductance, Gr, in parallel with the membrane capacity, Cm. For synaptic regions, the synaptic input intensity is represented by the variables $\epsilon = G_{\epsilon}/G_r$ and $\mathfrak{J} = G_i/G_r,$ which are assumed to be independent of changes in membrane potential. The dependence of membrane potential on 8 and J follows from standard circuit theory; the equations have been presented and discussed elsewhere (Rall, 1964; Rall and Shepherd, 1968). The 1968 reference also provides the specific pair of coupled nonlinear differential equations that was used to generate transient changes of \mathcal{E} and \mathcal{J} in active membrane. Such computed transients of & and I may be thought of as corresponding roughly to the transients of sodium and potassium conductance in the Hodgkin and Huxley (1952) model for active nerve membrane; they proved capable of generating and propagating well-shaped action potentials.

FIGURE 2 Diagram of the electrical equivalent circuit used to represent the lumped membrane parameters of a single compartment, in the compartmental models of Figures 1 and 3. The membrane current, I_m , flows through four parallel pathways provided by three conductances, G_r , G_ϵ , and G_j , and by the capacity, C_m . G_r represents the resting membrane conductance and lies in series with the resting EMF, or battery, E_r . G_ϵ represents an excitatory conductance which lies in series with an excitatory EMF, or battery, E_ϵ . Also, G_j represents an inhibitory, or quenching, conductance which lies in series with its corresponding EMF, or battery, E_j The resistor, r_i , represents the intracellular (core) resistance that joins one compartment to the next. (See Rall, 1964, and other references cited in the text.)

AXON, SOMA, AND DENDRITES Figure 3 shows three diagrams that preserve axonal, somatic, and dendritic regions of a neuron. Although these diagrams have been used to represent a mitral cell of olfactory bulb, they obviously have more general applicability. When the several dendrites (Figure 3A) are combined into an approximately equivalent cylinder, this system is reduced to one distance dimension (Figure 3B), but there is an obvious change in diameter from axon, through soma, to the (dendritic) equivalent cylinder. The compartmental abstraction (Figure 3C) indicates not only changes in diameter, but also a difference in membrane properties. The blackened compartments (axon and soma) are assumed to have active membrane properties; the dendritic compartments have passive membrane properties in some computations and active membrane properties in others.

SIMULATION OF ANTIDROMIC ACTIVATION The purpose in assembling these various component models was to generate (with a digital computer) a fairly realistic sequence of

FIGURE 3 Schematic diagrams of successive abstractions of a mitral cell, or of another cell of this general type. A. Axon, soma, primary dendrite, and several (truncated) secondary dendrites of such a cell. B. The dendrites of A are represented as an approximately equivalent cylinder; the soma appears as the transition from the small-diameter axon cylinder to the large-diameter combined dendritic cylinder. C. This compartmental model corresponds to A and B above; the three axonal compartments and the soma (all shown in black) are assumed to have active membrane properties; the dendritic compartments are assumed to have passive membrane properties in some computations and active membrane properties in others.

the membrane states that occur during antidromic activation of a single representative mitral cell. A suprathreshold depolarization of the distal axonal compartment results in the generation of an action potential that propagates from one axonal compartment to the next. It took special care to insure that this propagating impulse did not fail to invade the soma compartment. This is because the rate of depolarization is much slower in the soma compartment than in the axonal compartments, for two reasons: (1) the soma compartment has a larger electrical capacity, but, even more important, (2) the spread of current from the soma into the dendritic compartments provides heavy damping to the soma. We could reduce this damping by reducing the size of the dendritic compartments or by providing the dendritic compartments with a small background level of depolarization or of synaptic excitation, or by doing both. When the soma does fire an action potential, membrane depolarization spreads out into the dendritic compartments, either rapidly and without decrement in active dendritic membrane, or more slowly and with some electrotonic decrement in passive dendritic membrane. We computed many variations of such antidromic activation and used them as the basis for calculations of the associated extracellular potential distributions.

SYNCHRONY AND SYMMETRY OF POPULATION The key to the computation of the extracellular field potentials is provided by a consideration of the synchrony of activation in the neuron population and the geometric symmetry of the cortical anatomy. Figure 4A indicates the arrangement of the mitral-cell population in the olfactory bulb of rabbit. A single strong shock to the lateral olfactory tract initiates essentially synchronous antidromic activation of the mitralcell population. The somas of these mitral cells lie in an almost spherical shell, and their primary dendrites are directed radially outward. It is useful to consider the implications that follow when this approximate spherical symmetry is idealized to perfect spherical symmetry, as indicated diagrammatically at the upper right (Figure 4B). Given complete symmetry and synchrony, with equally spaced mitral cells generating identical amounts of extracellular current, it follows that the current generated by each of these mitral cells will be confined to a small (conical) volume element, such as the one indicated in Figure 4B. Because the number of such mitral cells is very large, these conical volume elements are thin slivers, and the extracellular current flow has an essentially radial orientation in the sphere. Because of the symmetry, no current can flow outside the sphere from one region to another, which is an example of the "closed field" characterized by Lorente de Nó (1947); see also Rall (1962b) and Rall and Shepherd (1968) for additional details on this point.

PUNCTURED SYMMETRY That the actual olfactory bulb is not a completely closed sphere is significant because of the even more important fact that the experimentally observed field of extracellular potentials is not closed. Specifically, a microelectrode at the bulb surface detects a significant transient of potential, relative to a distant reference electrode, during synchronous mitral-cell activation. This means that some of the extracellular current generated by the mitral cells must flow away from the bulb surface; it can return through the bulb puncture. This secondary extracellular current is indicated in the diagram at lower left (Figure 4C); the primary extracellular current is confined within each conical volume element. The equivalent circuit, at lower right (Figure 4D), shows both the primary extracellular current (PEC) and the secondary extracellular current (SEC) produced by a generator of extracellular current (GEC), which is shown as a compartmental neuron model.

POTENTIAL DIVIDER EFFECT The secondary extracellular current path has a finite resistance, and the distant reference electrode is effectively situated somewhere along this resistance; this reference electrode divides the over-all potential difference into two parts. For this particular application to the olfactory bulb, the resulting potential divider ratio of outer resistance to puncture resistance is about 1:4. Consider, for example, the moment at which synchronous mitral activity generates extracellular current such that the extracellular potential at the depth of the mitral-cell bodies is 2.5 mV negative relative to the potential at the dendritic terminals; the 1:4 potential divider ratio then implies 0.5 mV across the outer resistance, and 2.0 mV across the puncture resistance. Therefore, when recording relative to the reference electrode, a microelectrode placed near the dendritic terminals should be 0.5 mV positive, and a microelectrode placed at the depth of the mitral cell bodies should be 2.0 mV negative. Such values are observed experimentally, and this potential divider effect represents an essential part of the computational model. The diagram at lower right (Figure 4D), by a combination of the compartmental model of Figure 3C with the punctured symmetry considerations of Figure 4C, provides a compact representation of the several theoretical models that have been combined in the computational model for the olfactory bulb field potentials. My reason for presenting these details is based on a belief that this combined model (with different potential divider ratios) can be applied to synchronous activation in other cortical structures; a recent example is an application to the cerebellum by Zucker (1969).

EXPERIMENTAL POTENTIALS TO BE INTERPRETED Figure 5 shows how the experimental recordings obtained by Phil-

FIGURE 4 Diagrams related to cortical symmetry and to synchronous activation of the mitral-cell population. A. Schematic diagram of the experimental recording situation. The microelectrode (ME) penetrates the olfactory bulb; the reference electrode (RE) is distant. The mitral cells are arranged in an almost spherical cortical shell; their axons all project into the lateral olfactory tract. Single-shock stimulation to the lateral olfactory tract results in synchronous antidromic activation of the mitral-cell population. Circle with slanted arrow, here and in D, represents the recording system. B. Diagram of complete spherical symmetry of a cortical arrangement of mitral cells. The cone indicates a volume element associated with one mitral cell; the arrows indicate extracellular current generated by this mitral cell; the current is confined within its cone when activation is synchronous for the population. C. Diagram of punctured spherical symmetry. The arrows inside the cone represent the primary extracellular current generated per mitral cell; the dashed

line (with arrows) represents the secondary extracellular current per mitral cell. The location of the reference electrode (RE) along the resistance of this secondary pathway serves as a potential divider. D. Diagram combines the potential divider aspect (C) with a compartmental model (from Figure 3C). The relations of both the microelectrode (ME) and the reference electrode (RE) to the primary extracellular current (PEC) and the secondary extracellular current (SEC) are shown. The generator of extracellular current (GEC) is a compartmental model representing the synchronously active mitral-cell population. The solid arrows next to the compartmental model represent the direction of membrane current flow at the moment of active, inward, soma-membrane current (heavy black arrow); the dendritic membrane current is outward. The open arrows represent the direction of extracellular current flow (both PEC and SEC) at this same moment.

lips, Powell, and Shepherd (1961, 1963) were related to four depths in the cortical structure. These field potentials, recorded in response to synchronous antidromic activation, were found to be highly reproducible; thus we regard this potential as a function of two variables, depth and time. Because Shepherd has already presented olfactory bulb anatomy, I simply point out the four depths: the glomerular layer (GL), the external plexiform layer (EPL), the mitral body layer (MBL), and the granular layer (GRL). At first we concentrated on time periods I and II, to see if we could predict the same dependence on depth and time from our computational model for synchronous antidromic activation of the mitral-cell population. Later we turned to a consideration of time period III.

COMPUTED RESULTS FOR MITRAL POPULATION Figure 6 summarizes the results of a computation which simulated the synchronous antidromic activation of the mitral-cell population. This computation was based on the concepts already summarized in Figure 4C. This particular computation assumed passive dendritic membrane. An action potential was initiated in the most distal axonal compartment and propagated to the soma (shown as compartment 4 in Figure 6). The transient at lower left shows the transmembrane action potential (intracellular potential relative to extracellular potential) at the soma compartment. Above this are shown the transmembrane potential transients that spread into the dendritic compartments-an example of passive electrotonic spread from an active soma into passive dendrites. During period I, the soma membrane is more depolarized than the dendritic membrane, and the intracellular current flows from soma to dendrites, which means that the extracellular current must flow from dendrites to soma. This provides an intuitive explanation of the computed extracellular potentials during period I, shown in the right half of Figure 6. During period II, the active repolarization

FIGURE 5 Experimental field potentials shown in relation to histological layers. A voltage transient is shown at right for each of the four histological layers at left. The schematic Golgi histology at left shows two mitral cells (m) and two granule cells (g). GL designates the glomerular layer; EPL, the external plexiform layer; MBL, the mitral-body layer;

and GRL, the granular layer. I, II, and III designate three time periods used to facilitate the analysis and discussion of the voltage transients; the time scale at the lower right is in milliseconds. The + and - signs indicate polarity recorded at the microelectrode, relative to the reference electrode.

FIGURE6 Computed voltage transients obtained from equations corresponding to the diagrammatic combined model of Figure 4C. Nine compartments, shown on the left, were used in the computations, but results are illustrated for only three of these: compartment 4 as soma, compartment 6 as mid-dendritic, and compartment 9 as dendritic terminals. The three transients on the left represent passive electrotonic spread of intracellular potential from a soma action potential into passive dendritic compartments. The two sets of tran-

sients on the right represent the corresponding extracellular potential transients; the middle column expresses extracellular potential relative to the terminal (GL) level; the column on the right shows the same extracellular potential differences re-expressed relative to the distant reference electrode (potential divider effect). Time scale designates periods I and II; GL, EPL, and MBL designate the same histological layers as in Figure 5.

of the soma membrane makes the soma less depolarized than the dendritic membrane, and the intracellular current flows from dendrites to soma, which means that the extracellular current also becomes reversed and flows from soma to dendrites. This provides an intuitive explanation of the computed extracellular potentials during period II. The far right column of Figure 6, based on a potential divider ratio of 1:4, can be seen to provide a first approximation to periods I and II of the experimental transients shown in Figure 5.

SIGNIFICANCE OF DIFFERENT DEPTH DISTRIBUTIONS AND RELATIVE RESISTANCES The depth distribution of potential during time period III differs significantly from that of periods I and II. The schematic diagrams in the right half of Figure 7 were designed to illustrate the argument that activity in the mitral-cell population can account for the extracellular potential gradients during most of periods I and II, but that such activity cannot account for the extracellular gradients of potential during period III. Furthermore, the depth distribution of potential during period III could result from appropriate activity in the population of granule cells.

During periods I and II, large gradients of extracellular potential are present in the EPL, from GL to MBL, but not deeper in the granular layer, GRL. This experimental find-

FIGURE 7 Depth distribution of potential, and equivalent cylinders corresponding to different neuron populations. The field potentials on the left are the same experimental records as in Figure 5. The three diagrams on the right show equivalent cylinders and the direction of electric-current flow at three different times—period I, period II, and period III. The arrows show intracellular current, membrane current, and primary extracellular current; secondary extracellular cur-

ing was predicted by our computations, the essential reason being that the mitral axon has a much smaller area of cross section (and hence a much larger intracellular resistance, r_1 , per unit length) than does the equivalent mitral dendritic cylinder. The ratio is estimated to lie in the range 1:25 to 1:50. As indicated in Figure 7 (middle two diagrams), this means that significant mitral-cell extracellular current is generated only between GL and MBL, and negligible mitral-cell extracellular current is generated in GRL. This quantitative agreement between theory and experiment was found not only for the peak gradients of periods I and II, but also in the negligible contribution to the early portion of the GRL transient that was made by the propagating axonal action potential.

rent is not shown. GL, EPL, MBL, and GRL designate the same histological layers as in Figure 5. In both I and II, the large cylinder extending from GL to MBL corresponds to the combined dendrites of the mitral-cell population, and the thin cylinder extending from MBL into GRL corresponds to the mitral axons. In period III, the long cylinder extending from EPL far down into GRL corresponds to the large population of granule cells.

It was the quantitative agreement between theory and experiment during periods I and II that convinced us of the impossibility of accounting for period III in terms of current generated by mitral cells. During period III, the gradient of extracellular potential reaches far down into the granular layer; it has its maximum value near MBL. The kind of equivalent cylinder that could generate such current is shown at the far right in Figure 7; it must provide an effective intracellular conductance down into the granular layer. Although individual granule cells are small, the granule-cell population is very large. The granule cells have the required depth distribution; no other sufficiently numerous type of cell has this depth distribution. Thus we were forced to conclude that the major generator of extracellular current dur-
ing period III must be the large population of granule cells.

GRANULE-CELL ACTIVITY To generate the current flow shown in III in Figure 7, the granule-cell population could either undergo membrane depolarization in the EPL, membrane hyperpolarization in the GRL, or both. We were led to postulate synaptic excitation of the granule dendrites in the EPL as the primary activity leading to the generation of period III. Some synaptic inhibition could also be present at the deep granule-cell processes in GRL, but this was ruled out as the primary activity for two reasons: (1) such synaptic inhibition would not fit well with subsequent mitral-cell inhibition by granule cells, for which Shepherd (1963) already had experimental evidence; (2) such synaptic inhibition seemed less likely to generate a sufficient magnitude of current to account for period III. It should be added, however, that such synaptic inhibition of deep granule-cell processes could play an important secondary role of preventing action potential propagation in those granule-cell computations that include active membrane properties for the granule cells. One of the interesting findings of our granule-cell computations was that even with a "cool" version of active membrane kinetics, the resulting propagation (in the absence of synaptic inhibition) of active membrane depolarization was incompatible with the monophasic, spatially stationary character of the field potential observed during period III. The simplest successful granule-cell computations were obtained by assuming passive granule-cell membrane.

TWO-WAY DENDRODENDRITIC SYNAPTIC POSTULATE Thus, our quantitative fitting of theory to experiment convinced us that the granule-cell population must receive massive synchronous excitation delivered to the granule dendrites in the EPL. Phillips, Powell, and Shepherd postulated that granule cells inhibit mitral cells, but they implicitly assumed that the granule cells would be conventional in receiving their synaptic input at one region, propagating an impulse to another region, and then initiating synaptic inhibition there. By ruling out impulse propagation as predominant during period III, we required that synaptic excitation be delivered directly to the granule dendrites in the EPL. Although such could conceivably be done by recurrent axon collaterals of mitral cells (and we have not ruled them out as contributory), we were struck by the remarkable possibility, provided both by timing and by contiguity, that mitral secondary dendrites could deliver the needed synaptic excitation directly to the granule dendrites. That is, the depolarization of the mitral dendrites during period II is well timed to initiate the required synaptic excitation; also, Golgi preparations had demonstrated that the EPL is primarily a neuropil composed of these two kinds of dendrites.

Thus, we formed the postulate of two-way, dendroden-

dritic, synaptic interactions before we learned any of the details that were provided by electron-microscope studies of others. We postulated that membrane depolarization of the mitral secondary dendrites would initiate synaptic excitation, delivered from mitral to granule dendrites, and that the resulting membrane depolarization of the granule dendrites would then initiate synaptic inhibition, delivered from granule dendrites to mitral dendrites and somas.

ELECTRON-MICROSCOPE EVIDENCE It would be disingenuous to pretend that we were not pleased and excited when this two-way, dendrodendritic, synaptic postulate was provided with confirmatory histological support and elaboration by the electron-microscope findings of Reese and Brightman, who had been conducting an independent study of the olfactory system. These histological findings and our theoretical postulate complemented each other so well that we agreed to present them jointly (Rall et al., 1966). While preparing that joint paper, we learned of the similar histological findings of Hirata (1964), Andres (1965), and, later, of Hama (personal communication).

The schematic Golgi diagram (Figure 8A) shows only one mitral cell and one granule cell and indicates the intermingling of their dendrites in the external plexiform layer (EPL). A large number of additional granule cells and mitral cells (not shown in this diagram) essentially fill the EPL with a dense neuropil composed primarily of these two kinds of dendrites. In the Golgi diagram (Figure 8A), the open circle designates, at low magnification, the structures shown at higher magnification in Figure 8B, in which a granule-cell gemmule (GG) arises from a granule-cell dendrite (GD) and makes contact with a mitral secondary dendrite (MSD). This drawing (Figure 8B) was prepared from electronmicroscope serial sections; the two exploded views reveal two different synaptic contacts between the gemmule (GG) and the mitral dendrite (MSD). The contact on the left has vesicles clustered close to the mitral side of its contact region; by the established criterion (Palay, 1958; Gray, 1959), this contact is assigned the polarity mitral-to-granule as indicated by an arrow. The other contact has vesicles clustered close to the granule side of its contact region; by the same criterion, this contact is assigned the polarity granule-tomitral as indicated also by an arrow. In a quantitative study, based on many reconstructions from serial sections, all taken from one small region of the EPL, Reese (1966, 1970) found that most of the gemmules make such pairs of synaptic contacts of opposite polarity.

Our postulate that the mitral-to-granule synaptic contacts are excitatory, and that the granule-to-mitral synaptic contacts are inhibitory, was based not on morphological criteria, but on the theoretical considerations outlined in the preceding section. Nevertheless, it is interesting that our as-

FIGURE 8 Dendrodendritic synaptic contacts at two magnifications. A. Schematic Golgi histology, similar to that shown in Figure 5 but with emphasis on the external plexiform layer (EPL). The circle designates an example of a mitral secondary dendrite touching the gemmule of a granule dendrite, corresponding to the higher magnification shown in B. B. Drawing based on electron microscopy. The mitral secondary dendrite (MSD) touches a granule cell gemmule (GG) the stem of which is a process of a granule-cell dendrite (GD). This drawing by Mrs. G. Turner represents a reconstruction from 23 consecutive serial sections less than 0.1 micron in thickness, prepared and assembled by T. S. Reese. Two exploded views serve to reveal two synaptic contacts of opposite polarity, as indicated by vesicles and by arrows. Further details in Rall et al., 1966; Reese, 1970. signment of synaptic excitatory and synaptic inhibitory function is consistent with the two tentative morphological criteria that are currently being developed and explored. One criterion depends on the presence or absence of postsynaptic dense material. The other depends on a distinction between spherical and flattened vesicles; (See Price, 1968, for evidence on the vesicles and for references on both tentative criteria.)

Discussion

Two-wAY, DENDRODENDRITIC SEQUENCE The reaction of several neuroscientists, on first sight, was to regard such oppositely oriented synapses adjacent to each other as a short-circuit which could have no useful function. Such an objection disappears, however, when temporal sequence is taken into account. Our interpretation can be summarized with the help of Figure 9.

Whenever a mitral-cell body fires an impulse, whether it has been activated by the antidromic or the orthodromic route (AD or OD in Figure 9D), it results in a spread of membrane depolarization into the mitral-cell secondary dendrites. This depolarization takes place whether one assumes active or passive dendritic membrane properties. As can be verified in Figure 6, such dendritic membrane depolarization begins in the later portion of period I and extends through period II. The schematic sequence (Figure 9A, B, C) summarizes the postulated sequence of synaptic interactions. Depolarization of mitral-cell dendritic membrane activates mitral-to-granule synaptic excitatory contacts. The resulting membrane depolarization of the granule gemmules activates granule-to-mitral synaptic inhibitory contacts. Such synaptic activity inhibits the mitral cell and causes membrane hyperpolarization of the mitral-cell dendrites and soma. It is important to supplement Figure 9 with the reminder that every mitral cell is in contact with the gemmules of many granule cells, and every granule cell is in contact with many mitral cells.

SELF INHIBITION AND LATERAL INHIBITION It is evident that such two-way, dendrodendritic, synaptic interactions provide a negative feedback (recurrent inhibition) both to the mitral cells that have just fired impulses, and to any neighboring mitral cells that may not have fired. The selfinhibition feature, and the result that the granule-cell population can exert a damping effect on the entire mitral-cell population, could account (at least in part) for two phenomena: (1) an adaptive adjustment of the system to a wide range of input intensity; and (2) a tendency for rhythmic activity in the olfactory bulb. Also, because secondary dendrites of the mitral-cell extend laterally for long distances, it is likely that this mechanism can provide significant spatial

FIGURE 9 Schematic summary of postulated dendrodendritic synaptic interactions. A, B, and C show a single granule-cell gemmule (hatched) in contact with a mitral secondary dendrite (cylinder); a pair of synaptic contacts is indicated by thickenings in black. A. Membrane depolarization (D) of the mitral-cell dendrite during late period I and period II activates the mitral-to-granule synaptic contact (arrow) to deliver synaptic excitation (E) to the gemmule during period II. B. The resulting depolarization (D) of the gemmule then activates the granule-to-mitral synaptic contact (arrow) to deliver synaptic inhibition (I) to the mitral dendrite. C. During period III, the synaptic inhibition (J) can cause both hyperpolarization (H) and inhibition of the mitral dendrite and also of the mitral soma. D. Several gemmules of a granule cell are shown in contact with the dendrites of two mitral cells. A mitral cell can be activated either antidromically (AD) or orthodromically (OD). When the mitral soma generates an action potential, membrane depolarization spreads out into the mitral secondary dendrites, either passively or actively. This membrane depolarization of the mitral dendrite causes synaptic excitation to all granule-cell gemmules in contact with this mitral cell. The synaptically excited granule dendrites then deliver synaptic inhibition to all the mitral cells with which they are in contact, including mitral cells that did not contribute to this activity.

gradients of lateral inhibition (see Ratliff, 1965), which might contribute to olfactory discrimination.

AMACRINE CELLS By definition, an amacrine cell is a neuron that possesses no axon. The possible function of such neurons has troubled neuroscientists in the past. Our interpretation of granule-cell function in the olfactory bulb is therefore of some general interest. The function we envisage requires neither an axon nor an action potential in such cells; their synaptic interactions are transacted locally and probably in a graded, nonimpulsive manner. Axons and all-ornone action potentials are needed when information must be transmitted over a long distance, from one portion of the nervous system to another. Action potentials are not, however, needed in dendrites if their electrotonic length (L = ℓ/λ) values are less than about 2.

Two further points deserve emphasis. To function, the dendrites of such cells must both send and receive information. Also, the lack of an impulse provides for slow, graded activity which could serve as a rudimentary short-term memory, i.e., a weighted spatiotemporal integral of previous and surrounding levels of input, in which the weights of contributions decrease both with distance and with time.

OTHER AMACRINE CELLS The analogies between the olfactory bulb and the retina are not elaborated here; they are presented and discussed in Shepherd's chapter (this volume). The amacrine cells of octopus brain have been studied by Gray and Young (1964), who have postulated that these cells function as inhibitory interneurons and that they are important to the memory system of octopus. Quite recently, Best and Noel (1969) have observed reciprocal synaptic arrangements in the neuropil of planarian brain and have noted their possible significance.

COMMENT ON GRADED SYNAPTIC ACTIVATION Questions are often asked about our assumption that these dendrodendritic synapses can be activated in a graded manner. Many persons have been under the impression that only a presynaptic action potential is capable of triggering synaptic activity. Our reply is in two parts. First, our experimental and theoretical study has strongly suggested that the granule dendrites do not generate action potentials in the EPL during period III, and that passive spread of depolarization into the mitral secondary dendrites can be significant in magnitude. Second, and probably more convincing to others, is that graded synaptic activation has been produced experimentally by means of graded membrane depolarization, both at the neuromuscular junction (Castillo and Katz, 1954; Liley, 1956; Katz and Miledi, 1965 and 1967) and at squid synapses (Katz and Miledi, 1966; Bloedel et al., 1966). Given such experimental "existence proofs," we believe

that our assumption of graded activation of the dendrodendritic synaptic contacts by nonimpulsive membrane depolarization can be regarded as tenable.

COMMENT ON NEURAL CIRCUITS Because neural circuits are often presented in diagrams in a way that suggests simple one-to-one-to-one sequences of neuronal somas connected by axons, it seems desirable to comment on this. Most neurons have extensively branched dendritic trees. At least, such dendrites provide the possibility of receiving from many different input sources. At most, some of these dendrites may also *send* information, and some may be involved in graded, long-lasting, two-way interactions with other dendrites. In other words, wherever there are dendrites, one must consider the possibility of spatiotemporal integration, differentiation, and even more complicated operations or computations. Most diagrams of neural circuits provide no hint of the richness of such possibilities.

Summary

As stated in the introduction, this contribution describes a general theoretical method which can be applied to different neurons and to various populations of neurons. It also describes the specific application of this method to the olfactory bulb, and explains how this led us to postulate twoway, dendrodendritic synaptic interactions in the external plexiform layer, between the dendrites of mitral cells and granule cells.

No mathematical details are presented here; these are available elsewhere. Diagrams and descriptive discussion are used to explain how considerations of dendritic branching, of electrotonic length, and of both passive and active membrane properties can be incorporated into a compartmental model representing the axon, soma, and dendrites of a neuron. Such a model was used for computing a spatiotemporal sequence of membrane states corresponding to antidromic activation of a representative mitral cell. Diagrams and descriptive discussion are also used to explain how considerations of cortical symmetry, and of synchronous activation in the mitral-cell population, together with a consideration of the reference electrode (location on a potential divider), can be incorporated into a model for computation of the extracellular field potentials.

The computed results obtained for synchronous antidromic activation of the mitral-cell population are shown to agree well with the early part (periods I and II) of the experimental records; such agreement provides useful insights for the interpretation of the experimental results. Special emphasis is given to the contrast in the depth distribution of the experimental field potentials when period III is compared with periods I and II; it is argued that mitral-cell activity could not account for period III; and it is concluded that activity in the granule-cell population must be the major generator of extracellular current during period III. Furthermore, it is explained that the polarity, the slow time course, and the spatial stationarity of the potentials during period III are best accounted for by massive synaptic excitation of the granule-cell dendrites in the external plexiform layer and by absence of action-potential propagation in these dendrites.

These theoretical results, when considered together with the previously known electrophysiology and Golgi histology, led us to postulate dendrodendritic mitral-to-granule synaptic excitation followed by dendrodendritic granuleto-mitral synaptic inhibition. Electron microscopy, done independently by others, has revealed synaptic contacts that could account for such two-way, dendrodendritic, synaptic interactions, and the latest electron-microscope studies further strengthen the plausibility of this interpretation.

The discussion restates the dendrodendritic sequence of membrane depolarizations and synaptic activations that we assume, and points out that the resulting mitral-cell inhibition could contribute to damping and rhythmic effects as well as to lateral inhibition in the olfactory bulb. Implications for amacrine cells include dendrites that send, as well as receive, synaptic information, and synapses that are presumably activated in a graded, nonimpulsive manner. In neural circuits and in interacting populations of neurons, the presence of dendrites opens possibilities of spatiotemporal integration, differentiation, and even more complicated operations or computations.

COMMUNICATION AND CODING IN THE NERVOUS SYSTEM

The complexity of neuronal circuitry is seen in this drawing, provided courtesy of M. E. and A. B. Scheibel and of Brain Research. It shows, in horizontal section, the intricate afferent, efferent, and intrinsic organization of a part of the mouse thalamus. Dr. José Segundo, contributing editor for this section, feels it is characterized by words of J. L. Borges: "... a growing, dizzying net of divergent, convergent, and parallel times."

51 Communication and Coding by Nerve Cells

J.P. SEGUNDO

AN EXPERIMENT in basic neurophysiology often consists of the study of the relations between two activities. These, which for purposes of this discussion are designated M and N, are selected because they either reflect links in a causal chain or, being influenced by common factors, serve as indicators of each other.

It is possible to conceive of a general relation, designated as R, which matches all M and N events (Figure 1). It is possible also to imagine that each event in R is described fully. Different subsets of M, N, and R may be considered. Some of these, M_L , N_L , and r_L , respectively, take place naturally in real life. Others, M_E , N_E , and r_E , respectively, are observed experimentally. The experimental events are selected by the investigator because they reproduce natural occurrences or because they may provide information about mechanisms, and usually are summarized by representative parameters (if spike trains, for example, by mean rates).

The relation R between the two activities can be approached prospectively or retrospectively (Figure 2). The prospective way is to observe in M a particular event, m, and then look for possible associations in N. It may be desirable to assign to each N event a probability of occurrence conditional for the given m; this value will depend on the mechanisms that underlie R. For instance, if the skin is in-

J. P. SEGUNDO Department of Anatomy and Brain Research Institute, University of California, Los Angeles, California

FIGURE 1 Schematic representation of a typical neurophysiological experiment. Heavy continous lines represent the complete relation (R), broken lines that which occurs in real life (r_L), and light continuous lines that observed experimentally (r_E). M, N pairs may be: skin indentationcutaneous afferent spike activity; postsynaptic spike activity; presynaptic spike activity-postsynaptic membrane potential; blood CO₂ concentration-EEG activity; state in the

diurnal cycle-eye movements; and so on. The relation r_E is often described probabilistically, because M_E and N_E do not correspond on a one-to-one basis. Respective sizes and positions of M, M_L , M_E , N, N_L , and N_E illustrate the possibility that events may not occur either naturally or experimentally, that events observed experimentally do not necessarily take place naturally, and vice versa.

dented by 200 microns, can 30 afferent spikes be observed and, if so, with what probability? (Figure 2B) (Werner and Mountcastle, 1965, 1968). This viewpoint applied to r_E is implicit in the current experimental strategy in which the investigator imposes certain conditions and then observes their effects.

The second, or "restrospective" approach is to recognize a particular N event, n, and then look for each of its possible associations in M. It may be desirable to assign to each M event a probability of occurrence conditional for the given n. This value will depend on R, as well as on the laws that govern M events and, perhaps, other issues. For instance, if 40 spikes were observed, could the delivered skin stimulus have been (among others *a priori* equally probable) an indentation of 400 microns and, if so, with what probability? This viewpoint applied to r_L reflects how a subject must proceed when using his sensory input to identify some stimulus condition (Fujita et al., 1968). The distinction between the two approaches is especially useful when M and N reflect links in a causal chain. When M and N are influenced by common factors and serve as indexes of each other, the two approaches are essentially similar. The corresponding probabilities will depend on the relations between the common influences and each of the M and N activities, as well as on the laws that govern the occurrences of the commoninfluence events.

FIGURE 2 A. Different approaches to the relations between two activities. Prospective (R): Given a particular M event, m, the observer must predict its possible N event consequences and their respective probabilities. Retrospective (R⁻¹): Given a particular N event, n, the observer must infer its possible M event causes and their respective probabilities. B. Relations between skin indentation stimuli and number of impulses in a monkey mechanoreceptive fiber. Stimulus-response matrix of tallies. Each column corresponds to a separate stimulus category: stimuli were allocated to 30 equal categories on the basis of probe displacement. Each row corresponds to a separate response category: responses were allocated to 23 equal categories on the basis of the number of the impulses within a specified period. Total number of stimuli and that of responses in each category are shown across the bottom row or down the rightmost column, respectively. The proportion of cases in each entry relative to the total in the corresponding column (or row) estimates the prospective probability of that re-

sponse given that applied stimulus (or the retrospective probability of that stimulus given that observed response). (From Werner and Mountcastle, 1965.) C. Relations between head roll in space and interspike interval mean in a cat lateral vestibular nucleus cell. The relations are represented by a probability density contour diagram over the position-mean plane; darker shadings correspond to higher densities. The densities along the constant abscissa line AA' corresponding to 5° SD (side down) are plotted as a histogram on the upper right; they estimate the prospective probabilities of the different mean intervals given that the head is rolled 5° SD. The densities along the constant ordinate lines BB' (30 msec mean interval, corresponding to a rate of 33.3/sec) and CC' (16 msec mean interval, corresponding to 62.5/sec) are plotted as clear and shaded histograms, respectively, in the lower right; they estimate the retrospective probabilities of the different roll positions given means of 30 msec and 16 msec, respectively. (From Fujita et al., 1968.)

С

COMMUNICATION AND CODING BY NERVE CELLS 571

Communication between nerve cells

The general concepts of communication are applicable to all situations in which one entity influences or relates to another (Shannon and Weaver, 1963). We envision the nervous system as a set of interacting components. Therefore, the formalisms of communication theory are appropriate for its study, because they comply with the goal desirable in any scientific endeavor—of having explicit critical evaluations of the assumptions, logic, and conclusions that are implicit in the thinking in the field.

Important entities in any communication scheme are the source that generates signals and the channel that transmits them (Khinchin, 1957; Shannon and Weaver, 1963). When the source and the channel-input alphabets differ, it is necessary to transform or "code" every sequence of letters from the former into a sequence of letters from the latter. The communication scheme involving a channel exclusively appears the most reasonable in many neurophysiological contexts: from the activity M, the activity N, and the relation R, the investigator extracts the channelinput alphabet, the output alphabet, and the corresponding probability measure, respectively. If he is also interested in a probability distribution over M, he may connect to the channel a source the alphabet of which is identical to that at the channel input and of which the probability measure is the desired one. Because relations between physiological variables can be composed or decomposed, and new sources and channels arise when source-channel connections are made, several schemes may be adjusted to essentially the same biological system.

All communication studies pose problems at technical, semantic, and effectiveness levels (Shannon and Weaver, 1963). At the technical level, the investigator is concerned with quantification of symbol transmission. This is achieved by information theory, a specialized branch of applied probability theory, in which the amount of information conveyed by an experiment is equated with the amount of uncertainty or entropy its outcome removes (e.g., Khinchin, 1957; Shannon and Weaver, 1963). Basic theorems often apply only when the source uncertainty is less than the channel capacity and the message is sufficiently long; when these conditions are not met, as could happen in nerve cells, the corresponding propositions are neither demonstrated nor intuitively obvious (Khinchin, 1957). At the semantic level, the investigator asks how precisely the transmitted symbols convey the "desired meaning"; at the effectiveness level, how successfully the received message elicits the "desired conduct."

Identification of a desired meaning or conduct in situations involving nerve cells has varying degrees of difficulty because of the anthropomorphic sense of the word "desired" and because of our limited knowledge of nervoussystem physiology. The desired meaning is clear for firstorder sensory fibers, the most likely function of which is providing information about the environment; so is the desired conduct for a motorneuron, the most likely function of which is muscle control. Such identifications are, on the other hand, unclear in areas in which functional role is uncertain. In such cases, the semantic and effectiveness analysis, although equally important, may be highly conjectural because of, and increasing with, our ignorance of the role of the structure in question. As more complex functions are involved, difficulties become more marked, perhaps reflecting the inherent shortcomings of our own understanding.

Uses of information theory

In spite of these semantic and effectiveness qualifications, it is desirable, in some situations, to go beyond the tacit recognition that some communication scheme applies, and it is meaningful actually to measure information. Particularly warranted are calculations performed with the aim of quantifying the capacity of neural systems to inform as to the stimuli they normally receive (Stein, 1967b). Useful examples are, among others, MacKay and McCulloch's (1952) demonstration that a synapse is capable of transmitting as much information in interval-coded as in binarycoded form, although it probably actually transmits less, and several calculations in the visual system (Fitzhugh, 1957; Grüsser et al., 1962). Stein (1967b) derived valuable approximate equations for neurons that reflect the intensity of a constant stimulus lasting t seconds by the number of spikes in t; their information-transmitting capacity relates to the interspike interval distributions and, for large t's, takes into account the interval serial correlations, the number of cells in parallel, and the response reproducibility. In this model, the transmitted information is maximized by a probability of stimulus-intensity occurrence that varies inversely with the standard deviation of the response to each, and that often is close to uniform over its range.

Naturally and justifiably, spike trains play a major part in this section of the book (see also Segundo, 1970). Pioneering statistical studies by Hagiwara (1949) and Katsuki et al. (1950) were followed by others on methods (e.g., Bayly, 1968; Cox and Lewis, 1966; Gerstein and Kiang, 1960; Kogan et al., 1966; Perkel et al., 1967a, 1967b; Perkel, this volume). Each parameter measurement must be clarified explicitly to avoid apparent discrepancies. The mean rate, for example, can be measured over a specified period or over a specified number of spikes. Commonly it is measured over the entire record, but more restricted periods or sets can be chosen for physiological reasons (Segundo et al., 1966; Segundo and Perkel, 1969), to approximate an average (Walløe, 1968), or arbitrarily. The "window," involving specified periods or intervals, can be opened at prescribed times (e.g., at every second or spike), or can be moved continuously (Segundo et al., 1966; Segundo and Perkel, 1969). All spikes can be equivalent (e.g., Werner and Mountcastle, 1965; Walløe, 1968), or each can be weighted. A rate weighted with a decreasing function of the time since its occurrence (Segundo et al., 1966; Segundo et al., 1968) reflects jointly the nonweighted rate that relates to the interspike-interval mean and the pattern that relates to other statistics. In each case, parameters have certain defining conditions and domain parts that physiologically are more relevant than others (Segundo and Perkel, 1969).

Afferents from touch spots and in the dorsal spinocerebellar tract (DSCT) inform about skin indentation and muscle length, respectively (Jansen and Walløe, this volume; Walløe, 1968; Werner and Mountcastle, 1965, 1968). Contingent on the degree to which the neural response depends on the stimulus, the information provided by observing only the neural response approaches more or less that which would be obtained by observing the stimulus. Stimulus response matrixes (Figure 2B) were constructed on the reasonable assumption of the significance of some nonweighted rate under steady-state conditions. (The informative value also of other one-cell and two-cell parameters, especially under continually varying conditions, is discussed below.) The information transmitted, or transinformation, increased in a bounded manner when there were increases either in the number of equally probable-stimulus categories (which thus tended to a continuous, uniform distribution), in the number of observed-rate categories (which also tended to a continuous distribution), or in the observation times (Figure 3A and B). Figure 3A also illustrates the relation of the experimentally found transinformations with the calculated maximum values (Stein, 1967b). The natural order of the IA afferent intervals offered advantages over randomly shuffled sequences (Figure 3A and B). In

FIGURE 3 A and B. Transinformations. Values are from DSCT cells (continuous line with black circles) and from mechanoreceptive fibers (continuous line with open circles) (Werner and Mountcastle, 1965), and were calculated by a stimulus-response matrix method. The maximum possible values (broken line) were predicted by Stein (1967b). The stimulus-response matrix method probably overestimates and underestimates transinformations for short and long observation times, respectively. Transinformations are greater when they correspond to DSCT spike trains with interspike intervals in the order in which they occur in nature (A) than when they correspond to hypothetical trains with the same intervals after they have been shuffled (B). The solid lines reflect calculations based upon other methods. C. Rate of information transfer. The rate exhibits a maximum. It is consistently greater for intervals in natural order (continuous line) than for shuffled ones (broken line). All abscissae are observation times. (From Walløe, 1968.)

DSCT cells, in which variability, convergence, divergence, and interdependence participate, loss of information about muscle length is small (Walløe, 1968). Transinformations (Figure 3C) are moderate for brief observations; they then increase steeply and finally level off. With DSCT cells, the mean-rate variability when the same stimulus is applied several times is comparable to that during each trial. Contrastingly, with utricular afferents, rates change from one trial to another (Vidal et al., in preparation); hence, accurate subjective estimates should be based on several statistics of each cell, on several distinguishable cells, or on both.

The single powerful excitatory junction is appropriate for deducing formulas that relate uncertainties to mean rates and patterns (Segundo and Perkel, 1969; Segundo et al., 1966). Calculations are simplified when the statistics of the presynaptic discharge, i.e., the generating probabilities, are known (Figure 4A). In the prospective situation, the observer knows the timing of recent influential EPSPs (defined below), but, when predicting, is uncertain whether the postsynaptic cell will fire. He can base a prediction on prospective probabilities that are estimated experimentally (Figure 4B). In the retrospective situation, the observer knows the recent postsynaptic behavior, i.e., whether a postsynaptic spike has occurred, but is uncertain when inferring the presynaptic timings immediately preceding that event. He can base an inference on retrospective probabilities that are estimated experimentally (Figure 4C). Prospective and retrospective uncertainties are minimized when they are expressed as joint functions of rate and pattern.

Hence, parameters defined in information theory and

FIGURE 4 Generating, prospective, and retrospective probabilities at a powerful excitatory junction. Whether the postsynaptic cell will fire after a particular EPSP (or presynaptic spike) is related to the timing of only a limited number of recent "influential" EPSPs (or presynaptic spikes), at the most. For a sequence of j + l brief events, timing is the ordered set of j first-order intervals i1, . . . , ij; span T is their sum $i_1+\ldots+i_j;$ pattern is the ordered set of j - l ratios $i_l/T, \ldots, i_j - l/T$; and mean rate is the ratio j/T, (or j + 1/T, as mentioned in Segundo et al., 1966). In order to plot on a plane, it is assumed that only three influential EPSPs have timing that involves only two intervals used as abscissa and ordinate (inset on the lower right). Higher probabilities are represented by darker shadings in the contour diagrams. Gradients in general, along lines through the origin, and along lines with -1slopes reflect probability dependence on timings, rates, and patterns, respectively. (Computer-simulated cases.) A: 'Generating" probability, i.e., probability that a set of influential EPSPs will exhibit a particular timing. This example corresponds to EPSPs driven by a Geiger counter

estimated experimentally can be used to quantify conclusions with physiological interest. Particularly, they permit investigators to measure the uncertainties that exist in certain situations, with and without knowledge of relevant physiological indexes. Moreover, they enable them to analyze precisely the influence of several issues: at an excitatory junction, for example (Segundo and Perkel, 1969; Segundo et al., 1966), the generating probabilities reflect factors that act on presynaptic spike production and conduction; the prospective probabilities reflect such junctional and postsynaptic aspects as PSP characteristics (size, shape, summation rules, and so on) and spike consequences (afterpotentials, refractory cycles, and so on); and the retrospective probabilities reflect all these properties.

Coding in the nervous system: Natural codes

Neurophysiologists apply the word "code" frequently, but less in the mathematical sense defined above than in one "borrowed from the common discourse" (Perkel and Bullock, 1968) and in use before the rigorous meaning was coined. Perkel and Bullock (1968) have defined it as the representation and transformation of information. More precisely, the relation R transforms, "codes," or "encodes" the M events into the N events (Figure 1), and the rules of this mapping constitute the code. The mapping "used" by the animal in the course of its normal life, i.e., the "natural code," is that implicit in the restricted relation $r_{\rm E}$; it is

(From Segundo et al., 1966.) B. "Prospective" probability, i.e., probability that a set of influential EPSPs with a particular timing will trigger a postsynaptic spike. C. "Retrospective" probability, i.e., probability that an observed postsynaptic spike was preceded by a set of influential EPSPs with a particular timing. Each of the three lower rows involves a different form of EPSP summation: linear (1), with EPSP reduction (2), and with EPSP augmentation (3). The reduction of closely placed EPSPs in B makes the timings with the shortest intervals (i.e., with the highest rates) prospectively (B) less effective in triggering possible spikes than those with intermediate intervals, and therefore, retrospectively (C) less likely to have triggered an observed spike. The highest prospective probabilities 1 and 3 are not found close to the origin, because if the interval between the early EPSPs in the influential set (i.e., the abscissa) is short, it is likely that there will be a postsynaptic spike early in the set and that, therefore, refractoriness will prevent the cell from firing again after the last EPSP in the set. (Also compare plots in Figure 164 of Segundo and Perkel, 1969.)

COMMUNICATION AND CODING BY NERVE CELLS

frequently limited to particular features (e.g., to a relation between rates) of the general code. This, we believe, is the sense in which it is said that a muscle length is coded as a mean rate (Jansen and Walløe, this volume), that a shift in presynaptic timing is coded as a change in postsynaptic firing (Segundo et al., 1966), and so on. The expression is particularly meaningful functionally when R involves a causal relation. The words "decoding" and "decoder," applied in communication (Shannon and Weaver, 1963) to the reconstruction of the original message from the signal and to the entity that performs it, may be misleading in a neurophysiological context if they imply that the resulting message is similar to the input (Perkel and Bullock, 1968); "reading" and "read-out mechanisms," respectively, would perhaps be clearer (Segundo and Perkel, 1969).

As the pertinent conditions vary over a certain space, which may well be continuous and nondenumerable, there are corresponding alterations in neuronal activity. (The possibly probabilistic nature of the relation between conditions and changes should not be forgotten.) Any neural change, for example, that which results from a shift in conditions from C1 to C2 (Figure 5A), is characterized by spatial or temporal features, or both. The spatial features (Figure 5B) arise when the different conditions C_1 and C_2 are reflected by different sets, S1 and S2, of nerve cells, the activities of which are outside pre-established control ranges. They have been discussed extensively for most sensory modalities (e.g., Creutzfeldt, this volume; Mountcastle, 1967). As pointed out by Werner (this volume), the geometrical properties of central mappings differ from those of the stimulus space and thus preclude simple correspondences. In somatosensory area I, small shifts in stimulus location lead to marked changes in the responding sets, because receptive fields of individual neurons are highly

FIGURE 5 Schematic representation of the spatial and temporal components of the neuronal response to a naturally occurring change. The natural change from C_1 to C_2 (A) may occur in some sensory situation, be the passage from sleep to wakefulness or from one endocrine state to another, and so on. The resulting neuronal response (B and C) is also natural, thereby complying with the first necessary requirement for being a useful part of a code in a living communication scheme. The other requirement is that there be elements (nerve cells or effectors) that respond to that change (see text). The spatial component of the response (B) involves the shift from the set S₁ to the set S₂ of "re-

sponding" neurons. The temporal component (C) involves changes in the activities of and in the correlations between, the cells in T, which is a part of the intersection of S_1 and S_2 . The discharges of two cells in T are represented below: on passing from conditions C, with activities T_1 , to conditions C_2 , with activities T_2 , each cell becomes faster and more regular, and each of the evenly spaced triplets in one (upper record) coincides in time with a single spike in the other (lower record). This Venn diagram carries no implications as to the actual topographical distributions in the nervous system of S_1 , S_2 , and T. restricted (e.g., Werner, this volume); contrastingly, in reticular nuclei, larger shifts are necessary to obtain significant changes, because fields are often less restricted (e.g., Segundo et al., 1967b). The temporal features (Fig. 5C) of the neural change arise when the conditions C_1 and C_2 are reflected by different activities or correlations, or both, in at least some cells responding to both. These also have been discussed.

Recognition that a particular neural change is, in some sense, a useful part of the natural codes in a neuronal communication scheme implies two necessary, but perhaps not sufficient, requirements (Segundo and Perkel, 1969). The first is to recognize that it occurs in normal life. This requirement is met in practice when the change from C_1 to C_2 is a natural one, i.e., occurs within a certain M_L subset, and the neural change, taken here as an N_L-activity shift, is observed experimentally in a preparation as physiological as possible (e.g., in a freely moving and unanesthetized animal). The second necessary requirement is that there must be neural or effector elements, the activity of which is modified by it (Perkel and Bullock, 1968; Segundo and Perkel, 1969; Segundo et al., 1968; Terzuolo, this volume; Uttal and Krissoff, 1968; Walløe, 1968). If none exists, the change constitutes a dead end, inconsequential as far as subsequent processing is concerned. This requirement implies that the same change, taken now as an M event, must modify the activity of certain neuronal or effector elements, i.e., must elicit a change in some N space. It will be met commonly tor the spatial features, because dissimilar sets usually distribute their influences differently; in fact, a neuron remains a "labeled line" (Bullock and Horridge, 1965; Perkel and Bullock, 1968) to the extent that its distribution and effects are unique. The requirement will be met for the temporal features, too, if certain cells respond differently to dissimilar presynaptic timings or correlations in a particular set of presynaptic terminals. Identification of temporal changes which are "read" by postsynaptic cells is thus an important physiological problem (Segundo and Perkel, 1969).

The neuron as an analyzer of spike trains

The presynaptic terminals that make contact with a particular postsynaptic cell, produce PSPs therein and influence a certain spike-trigger locus, can be classified in, or between, two extreme categories based on the size of their PSPs and on the manner of their influence (Segundo and Perkel, 1969; Segundo et al., 1968). In the first extreme category are terminals that elicit large PSPs, i.e., "powerful" terminals. The terms "large" and "small" are relative to the average voltage between membrane potential and threshold and apply to PSPs recorded at that spike-trigger zone (Segundo et al., 1963). This category has been analyzed extensively (Bittner, in preparation; Bullock and Horridge, 1965;

Gillary and Kennedy, 1969; Jansen and Walløe, this volume; Moore et al., 1963; Perkel et al., 1964; Ripley and Wiersma, 1953; Segundo et al., 1963; Segundo et al., 1966; Segundo et al., 1968; Segundo and Perkel, 1969; Walløe, 1968; Wiersma and Adams, 1950). These terminals influence the postsynaptic discharge by way of their interspike interval mean (and, therefore, mean firing rate), standard deviation, histogram, serial correlations, and so forth. The postsynaptic discharge, then, depends on both the presynaptic mean rate and its pattern, measured over either the entire train or through specified windows (see above). The general trend is for faster excitatory and slower inhibitory presynaptic rates to produce faster postsynaptic discharges (Figure 6). The terms "fast" and "slow" as applied to the input relate to such junctional and postsynaptic features as time constants and aftereffects of PSPs and spikes (Segundo et al., 1963; Segundo and Perkel, 1969; Segundo et al., 1966; Terzuolo, this volume). Figure 6 represents findings in many pacemaker nerve cells either computer-simulated or living, such as those in molluscan ganglia and in crustacean stretchreceptor organs (but not necessarily in all of them, Terzuolo and Bayly, 1968). Irregular inputs produce monotonic curves. Regular inputs lead to zigzag curves with oppositely sloped segments that imply such special results as "paradoxical" rate changes and disproportionate effects (Moore et al., 1963; Perkel et al., 1964; Schulman, 1969; Segundo and Perkel, 1969). Changes around extreme rate values are usually insignificant, because it is not possible to go beyond stopping the cell or driving it maximally.

The pattern is influential at intermediate rates (Figure 7, top, page 579) (Moore et al., 1963; Perkel et al., 1964; Segundo et al., 1963; Segundo and Perkel, 1969; Segundo et al., 1966; Segundo et al., 1968). The separation of the curves in Figure 6 illustrates a sensitivity to variability, and the time structures of input trains at given mean rates influence the output of simulated DSCT and granule cells (Jansen and Walløe, this volume; Walløe, 1968). Greater presynaptic and postsynaptic irregularities commonly, but not always, go together (Hegstad, Segundo, and Perkel, in preparation; Segundo and Perkel, 1969; Segundo et al., 1968). Certain timings exert the maximum effect under each set of restrictions (Segundo and Perkel, 1969).

The input-output relation can be explored in detail when a single strong terminal excites a nonpacemaker cell (Segundo and Perkel, 1969; Segundo et al., 1966). At each instant, the latter bases the decision of firing on an evaluation of the timing, i.e., of the mean rate and pattern, of the EPSPs within a bounded period, and, therefore, of a restricted number of them. (The decision to fire also is biased by recent previous postsynaptic discharges.) The boundedness of the "integration" period reflects those of the postsynaptic time constant and of the presynaptic terminal excitability cycles; the restriction on the number of "influential" PSPs

FIGURE 6 Influence of presynaptic mean rates. Computer simulation of a single powerful presynaptic terminal acting on a postsynaptic pacemaker cell (the spontaneous rate of which is about 2 per sec). On the abscissa, presynaptic mean rates conventionally affected by a positive or negative sign if corresponding to EPSPs or IPSPs, respectively. On the ordinate, postsynaptic mean rate. Broken lines correspond to irregular, and solid lines to regular, presynaptic train patterns. Graphs were drawn by hand on the basis of more than 150 points. The general trend is for "higher"

reflects the facts of a bounded integration period and of presynaptic refractoriness. A mean rate weighted exponentially according to physiologically suggested parameters is, in this case, a functionally meaningful description (Segundo and Perkel, 1969).

The order in which terminals are activated may be influential, even beyond the obvious example that large IPSPs are more effective when they precede EPSPs (Hegstad et al., in preparation). Indeed, EPSP summation may be noncommutative (Gerstein, this volume; Segundo et al., 1963), and invertebrate neurons with segregated input zones separating spiking regions may "sense" stimulus direction and velocity (Kennedy and Mellon, 1964).

In the other extreme category of presynaptic terminals are those that elicit small PSPs, i.e., "weak" terminals (Segundo and Perkel, 1969; Segundo et al., 1968). Their contribution is demonstrated easily only if they are numerous. The degree of interterminal correlation is a critical issue under these conditions. The discharges of cells A and B are said to be "correlated" when, as estimated by the crosscorrelation histogram, there is, within a certain time from an A spike, a different-from-average probability that B will

presynaptic rates, i.e., slower IPSPs or faster EPSPs, to produce faster postsynaptic discharges. The irregular patterns produce a monotonic curve; the regular patterns produce a zigzag curve with oppositely sloped segments. This leads to special results, such as a sensitivity to variability, "paradoxical" rate changes, and some disproportionate effects (see also Segundo and Perkel, 1969). Comparable displays can be constructed for other variables (e.g., presynaptic rate-postsynaptic standard deviation). (From Perkel et al., 1964.)

fire (Perkel et al., 1967b). When, on the one hand, the weak terminals are independent, their influence arises exclusively from their summed mean rates and not from other discharge parameters (Figure 7, center). When, on the other hand, the weak terminals are correlated, their influence reflects other statistics in addition to mean rates (Figure 7, bottom) (Hegstad et al., in preparation; Segundo and Perkel, 1969; Segundo et al., 1968). This holds even if the dependence is of physiological degree, involves only some terminals, or occurs within separate groups.

Correlation between converging terminals is, therefore, most important physiologically (Figure 8, page 580). It arises because of shared influences (which may depend on common sensory drives, e.g., Gerstein, this volume; Terzuolo, this volume), or synaptic connections (Aladzhalova et al., 1969; Moore et al., 1970; Person, 1965; Vasilevsky, 1968), or both. Each anatomical-functional arrangement (in terms of cell properties, synaptic effects, and correlations with other cells) determines a characteristic cross-correlation histogram, but the converse is not true (Moore et al., 1970). Parallel correlated fibers with similar influences on the same post-synaptic cells (Figure 9A, 'page 581) may allow the

FIGURE 7 Influence of presynaptic patterns at similar mean rates. Interspike interval histograms of postsynaptic activities in computer simulation experiments in which the same pacemaker cell was submitted to inhibitory presynaptic influences that are either "irregular" (left column) or "regular" (right column). Single powerful presynaptic terminal (upper row), or 64 weak terminals that either are independent (center row) or have physiological degrees of correlation (lower row). All terminals have approximately the same mean firing rates; the powerful terminal elicits a large IPSP, and all 64 weak terminals elicit small IPSPs of about the same sizes. The postsynaptic activities corresponding to regular and irregular inputs differ with a single powerful terminal (upper row) and with 64 weak correlated terminals (lower row), but do not differ with 64 weak independent ones (center row). The irregular presynaptic terminals (lower left) have a stronger correlation than the regular ones (lower right). These cases were chosen because they

illustrate to the naked eye the difference in histogram shapes. However, weaker and more comparable degrees of correlation could still produce outputs that were significantly different. The effect of presynaptic correlation was clearer when the weak terminals excited a nonpacemaker cell, as discussed in Segundo et al. (1968), than when they inhibited a pacemaker cell as in this Figure. In these comparisons, statements as to similarities or differences were based on the application to the observed cumulative interval histograms of 90 per cent confidence-level tests of the hypothesis that both samples were from populations with the same distributions (Dixon and Massey, 1969). Unfortunately, and as illustrated by most references, tests for statistical significance of, for example, differences and goodness-of-fit have not been used extensively in this field. N. number of cases; μ , mean; σ , standard deviation; CU, coefficient of variation. (From Hegstad et al., in preparation.)

FIGURE 8 Correlated spike discharges. A. Cross-correlation histogram between the source of excitation, a Geigercounter-driven shock train to a connective trunk, and the spike train of an excited nerve cell. In this case, the evoked EPSP closely paralleled the higher-than-average histogram profile to the right of zero. B. Cross-correlation histogram between two pacemaker cells sharing an inhibitory influence elicited by a Geiger-counter-driven stimulation of a connective trunk. As does shared excitation (but in

a somewhat lesser degree), shared inhibition can produce a higher-than-average profile around the origin. The crosscorrelation histogram between two activities reflects the individual features of the cells, the anatomical-functional characteristics of their connection, and correlations with other neurons. Empirical confidence bands are obtained by shuffling the intervals at random. Unidentified cells in an isolated *Aplysia* ganglion. (From Moore et al., 1970.)

nervous system to use spatial averaging, thus abbreviating temporal processing (Fitzhugh, 1957; Gerstein, this volume; Maffei, 1968; Perkel and Bullock, 1968; Segundo et al., 1963; Stein, 1967a, and this volume; Terzuolo, this volume).

The preceding considerations suggest that, when sufficient knowledge about the anatomical and physiological properties of a junction is available (i.e., when PSP sign and summation rules, postsynaptic firing characteristics, synergistic inputs, and so on, are known), it will be possible to anticipate with acceptable certainty the correspondence between presynaptic and postsynaptic events, i.e., it will be possible to predict the corresponding code. The most general postsynaptic cell is that influenced by few powerful terminals and by larger numbers of intermediate and weak ones, with varying degrees of correlation (Segundo and Perkel, 1969).

The presynaptic mean rate is highly influential in neuronal input-output relations. This holds for the nonweighted rate over complete records or restricted sets (e.g., Figures

FIGURE 9 A. Advantages of parallel processing. The anatomical arrangements 1, 2, 3, and 4 exhibit increasingly complex excitatory connections (in 4, the paths from B cells to C cells are shown only for B_1 and B_{10} so as to make the Figure less intricate). Beneath each diagram is a histogram of the possible outputs in response to timings u (shaded histograms) and f (unshaded histograms) fired by neuron A₁. 1. The prospective probability of each B cell firing is 0.09 for u and 0.90 for f. 2. With 10 similar and noninteracting cells in parallel, u usually will elicit about one spike and f will elicit close to 10 spikes. 3 and 4. A

158, 167, and 170 in Segundo and Perkel, 1969). In certain cases, for example, with many independent terminals at similar rates, the nonweighted, over-all rate is the only influential statistic. In other cases, such as those with few powerful terminals or numerous correlated weak ones, other singlecell or two-cell intervals or count statistics (such as standard deviations, histograms, serial coefficients, autospectra, cross-correlation histograms, phase relations, and so on) become important, together with the non-weighted rate. Then the ongoing modulation of the presynaptic intervals (or instantaneous rates) around their average determines corresponding variations of the postsynaptic intervals. (The modulation itself reflects the upstream generation of large PSPs, of bursts of correlated small ones, special threshold characteristics, and so on; Segundo and Perkel, 1969). Certain aspects of these modulations are quantified by the crossspectral densities of the presynaptic and postsynaptic spike counts (Bayly, 1968; Cox and Lewis, 1966; Perkel, this volume; Terzuolo, this volume). The gain and phase shift

third order set of C cells is such that each is influenced by all B cells and will fire only if at least any five of them discharge almost simultaneously; this leads to the virtually certain outcomes of "no spike" for u and "10 spikes" for f. B. Switching" role of a neuron with different kinds of output junctions. If different inputs, A₁ and A₂, trigger B into producing different timings, B₁ and B₂, respectively, and each acts preferentially on a different set of postsynaptic cells, C₁ and C₂, respectively, the common neuronal link B may channel selectively different arriving influences down separate outflow channels. (From Segundo et al., 1963.)

of the transynaptic transfer of each periodic component depends on issues such as the relative lengths of its period and of junctional cycles and time constants. High gains and small phase shifts may not always be useful functionally. Linearity, even if defined satisfactorily, may, in this context, have a range that is no more than a small part of that of physiological variations. Nevertheless, a systems-analysis approach may serve to describe some of the time-invariant properties of the junction within linear limits (Perkel, this volume; Terzuolo, this volume).

Interspike-interval variability may or may not benefit the functional role of a particular cell. In sensory systems, for example, it may hinder information transmission about steady-states, but favor that about variable situations (Stein, 1967b, and this volume); thus, it can be undesirable or desirable, respectively. Shifts from constant to varying conditions often imply changes in the discharge of individual cells and, in addition, increased correlations: this happens in Ia muscle afferents (Jansen and Walløe, this volume; Terzuolo, this volume) and possibly explains the discharge independence of steadily illuminated, photosensitive crayfish neurons (Stark et al., 1969).

Valuable general suggestions have arisen from sensory neurophysiology in the form of evoked changes that reasonably should be "read" by the nervous system (e.g., Creutzfeldt, this volume; Mountcastle, 1967; Uttal and Krissoff, 1968). For instance, the fact (Mountcastle et al., 1969) that a vibratory stimulation to a specified region of the skin is coded jointly in a particular set of correlated cortical neurons as a rate and as an interval order that preserves periodicity, is strongly suggestive evidence for the significance of several statistics in sensory processes (Figure 10). Other possibly influential issues were reviewed by Perkel and Bullock (1968).

Mechanisms

Important aspects of the processes that determine the neuronal input-output relation affect the transmembrane potential value (Bittner, in preparation; Calvin, 1968; Gillary and Kennedy, 1969; Hartline and Cooke, 1969; Jansen and Walløe, this volume; Kogan et al., 1966; Levitan et al., 1968; Moore et al., 1963; Perkel, this volume; Perkel et al., 1964; Schulman, 1969; Segundo et al., 1966; Segundo et al., 1968; Terzuolo, this volume; Walløe, 1968). When large PSPs are elicited by few terminals, the postsynaptic response to changes in presynaptic timing is explained partly by straightforward arguments, which include shapes, as well as linear and nonlinear summation rules, about postsynaptic, pacemaker, and after-potentials (Segundo et al., 1963; Segundo and Perkel, 1969). The relation of the prospective probability and other probabilities with separate physiological issues is discussed above. If several terminals are independent, their combined sequence is almost Poisson, and therefore relates little to individual patterns (Segundo et al., 1968). There are no known examples of this with powerful terminals, the DSCT case probably differing because of "beating" between several inputs, which, although independent in the steady state, are not quite enough to compensate for their regularity (Jansen and Walløe, this volume; Perkel, 1965; Walløe, 1968). When the independent terminals are weak, their effect approximates that of a DC bias, under constraints involving average intervals, postsynaptic time constants, and so on (Hegstad et al., in

FIGURE 10 Coding of a vibratory stimulation as a periodic discharge timing within a specific set of correlated nerve cells. Autocorrelation histograms of the spike discharges of a neuron in the somatic sensory cortex of a monkey. Thirty-Hz sinusoidal stimulations were applied to the skin at ampli-

tudes indicated for each row at the extreme right. In the left column, the intervals are taken in their natural order. In the right column, the same intervals are shuffled. (From Mountcastle et al., 1969.)

preparation; Segundo and Perkel, 1969; Segundo et al., 1968; Walløe, 1968). When excitatory, they will therefore elicit regular firing unless issues such as accommodation are strong. If, however, they are not independent and fire synchronously, they will elicit larger oscillations, and therefore resemble powerful terminals in terms of their influence (Segundo et al., 1967a).

The membrane potential can be described by such measures as means, histograms, waiting times to reach threshold, and frequency spectra, among others (Calvin, 1968; Levitan et al., 1968; Segundo and Perkel, 1969; Walløe, 1968), the values of which depend on the sign (excitatory, inhibitory), size, and statistics (rate, regularity, and so forth) of the arriving impulses, as well as on such postsynaptic features as time constants, pacemaker and after-potentials, and other related phenomena. Greater potential fluctuations around similar averages are seen with irregular or serially correlated large EPSPs than with regular or uncorrelated ones at the same mean rates. One or the other pattern will be more effective, depending on the threshold (Figure 11A, B, C, page 584). Average potential values increase linearly with arrival rates in simulated granular cells, but the variability is less with naturally ordered than with shuffled inputs (Figure 11D). There is also a linear relation in Aplysia between the mean rate of the influential EPSPs and the probability of the postsynaptic membrane depolarizing by a certain amount (Figure 170 in Segundo and Perkel, 1969). The distribution of the membrane potential might play a role in normal operation by relating to the proportion of cells that fire to test EPSPs (Levitan et al., 1968). A membrane-potential distribution may be estimated for each time after a presynaptic spike or stimulus, and there may be clear parallelism between the median value profile, the evoked PSP wave, and the corresponding cross-correlation histogram (Segundo et al., 1967a).

The important roles in the junctional input-output relation of the postsynaptic spike-generating and related processes also have been analyzed (Jansen and Walløe, this volume; Segundo et al., 1963; Segundo and Perkel, 1969; Segundo et al., 1968; Terzuolo, this volume; Walløe, 1968). Postsynaptic refractoriness is responsible for certain multimodal interval histograms (Segundo et al., 1963; Segundo et al., 1968), for the shift of the maximum prospective probability from the lowest abscissae in the "passage through a certain level" plots to intermediate values in the "spike" plots, for certain unexpected absences of EPSP acceleration effects (see Figures 160 and 164, respectively, in Segundo and Perkel, 1969), and so on.

A single nerve cell may have more than one kind of terminal (Bittner, 1968; Jansen and Walløe, this volume; Kandel et al., 1967; Roeder, 1966). Hence, to a particular activity change in the same presynaptic cell there may be a corresponding, different activity shift in each of several postsynaptic elements, even when (as may not always be the case) the trains in the different terminals remain identical (Segundo et al., 1963; Segundo et al., 1966). In other words, each junction type of the same parent axon may have its own particular code and prospective and retrospective probability mappings. This widens the functional range of single cells, and may enable them to play a switching role, whereby at certain timings the cell may influence some postsynaptic units and channel its message down one pathway and at other timings it may affect a different postsynaptic set and path (Figure 9B) (Bittner, 1968; Bittner, in preparation; Segundo et al., 1963; Segundo and Perkel, 1969; Segundo et al., 1966).

Part of the role of neurons as devices that communicate and code is explained by a simplified conception that lumps the entire synaptic area and a unique spike-trigger zone at a single somatodendritic point, and is defined by simple potential and threshold dynamics. This conception, implicit in much current thinking, is also explicit in several models and simulations. Their operations on the input have been studied extensively (e.g., Geisler and Goldberg, 1966;Harvey, 1967; Jansen and Walløe, this volume; Perkel, 1965; Perkel et al., 1964; Segundo et al., 1966; Segundo et al., 1968; Stein, 1967a; Walløe, 1968). Some of their stages are reminiscent of low-pass filters (Terzuolo, this volume). There are, however, additional subtleties and issues, some well demonstrated, some hypothetical, as summarized by, for example, Bullock (1967), Bullock and Horridge (1965), Eccles (1964), and Segundo (1970). Although they play a minor role in certain cells, for which the simplified models are reasonable approximations, they are highly developed in others, and the corresponding behavior is far more elaborate. Hence, the simplified conception cannot be considered a complete description of all nerve cells. In fact, the large numbers and varieties of nerve cells, of operational modes, and of influences present in any nervous system, even at the simplest level, should remind the neuroscientist of the assertion by Teilhard de Chardin (1962) that, whereas some disciplines are concerned with what is very large and others with what is very small, biology in general and, I may add, the neurosciences in particular, explore the special dimension of that which is immensely complex.

FIGURE 11 Regular and irregular EPSPs at identical mean rates: Comparison of their effects on the membrane potential and their effectivenesses. A, B, C. Unidentified cell in Aplysia visceral ganglion. (Stimuli at 3 per sec.) The membrane potential oscillations during regular stimuli (A, upper record) had an average value of 10.7 mV (measured with respect to the resting value), a standard deviation of 2 mV, and a narrow, high, and relatively uniform histogram (B). The oscillations during irregular stimuli (A, lower record) had the same average of 10.7 mV, a standard deviation of 4.5 mV, and a broad, flat, and skewed histogram (B). The potential levels indicated as A and B on the records correspond to the values so labeled on the histograms. C. (Stimuli at 2 per sec.) In the records shown, where

the threshold is high, e.g., about A, no spikes are evoked by a regular excitation, but several occur during irregular stimuli. If, on the other hand, the threshold were low, e.g., around B, the regular input might keep the cell firing continually, but the irregular input would allow for pauses. (From Levitan et al., 1968.) D. Computer simulation of a single, powerful, excitatory DSCT terminal acting on a nonpacemaker cerebellar granule cell. Standard deviation of the value of the postsynaptic membrane potential as a function of the corresponding presynaptic mean rate. The membrane fluctuations are smaller when the sequence of the DSCT interspike interval reproduces that which occurs naturally (black circles) than when the same intervals are shuffled randomly (open circles). (From Walløe, 1968.)

52 Spike Trains as Carriers of Information

DONALD H. PERKEL

NERVE IMPULSES or "spikes" are a nearly ubiquitous accompaniment to neural functioning. Rejecting the idea that they are solely artifactual or epiphenomenal, we accept, rather, the notion that trains of impulses embody or carry information. Major questions arise immediately: (1) How do they carry information? (2) What kinds of information do they carry? (3) Where do they carry it from, and to? (4) What interprets the delivered information? (5) How well is the information carried? (6) What is the role of spike trains vis-à-vis other media of neural communication?

These questions are, of course, by no means independent. Moreover, the answers depend very much on which part of what nervous system is under consideration, as well as on the particulars of the experimental arrangement, especially with regard to surgical procedures, anesthesia, and the stimulus regimen.

We first draw a primary distinction between two kinds of information carried by spike trains (Segundo and Perkel, 1969): the information potentially available to the human investigator is of a different order and calls for different procedures of interpretation (e.g., statistical analysis) from the information normally extracted from a spike train by the next-order neural or effector element in the system. Thus, the experimenter can record and analyze very long trains of impulses, whereas the capacity of a neuron for temporally integrating its synaptic input is stringently limited. On the other hand, a neuron has access to all the synaptic input impinging on it, whereas with current techniques the electrophysiologist can record at most a handful of simultaneously detected spike trains, while having at best a rudimentary knowledge of the anatomical relationships among the corresponding neurons.

We may therefore investigate on the one hand the information extracted from spike trains in an ongoing fashion by a nerve cell that is "integrating" that information or "making decisions" based at least partially on that information; we may call this approach the "neuron-centered" study of neural coding in spike trains. The alternative approach emphasizes the information extractable by the experimenter. This "observer-centered" investigation addresses the problems of identifying the functional connections among the neurons of which the spike trains are observed, and of characterizing their corresponding input-output relations.

The proposed kinds of neural codes have been reviewed, enumerated, and summarized recently (Perkel and Bullock, 1968), and the criteria—formal and biological—for adequately describing their properties were discussed in terms of establishing that a candidate scheme of neural coding is, in fact, functionally valid in a particular nervous system. In this presentation, the relationship between several spiketrain codes is stressed in an effort to show that the particular operative information-encoding scheme depends on the context of information input to the system, and in particular on its characteristic modulation times relative to the interspike intervals of the observed neuron.

We retain here the working definition of neural coding as "the representation and transformation of information in the nervous system" (Perkel and Bullock, 1968), using the term "information" in its colloquial sense rather than with the technical meaning of Shannon.

Much of this chapter, therefore, is devoted to methods of extracting information from spike sequences. The statistical techniques are summarized, examples are given of their use in elucidating neuronal relationships, and, finally, new directions are indicated for extending and strengthening these techniques.

The variety of spike-train codes

The peculiarity of spike-train codes is that the information is carried by means of impulses: brief, discrete, virtually indistinguishable events, occurring most usually at irregular intervals. Hence, they differ from continuous "signals" such as the electroencephalogram, and from trains of pulses occurring at regular intervals or at multiples of a fixed interval, such as those flowing in a digital computer. It follows that, as bearers of information in nervous systems, spike trains have special characteristics, capabilities, and limitations.

The two "classic" spike-train codes have been called "labeled-line" coding and rate coding. The concept of labeled lines means, quite simply, that an essential aspect of the information conveyed by a nerve impulse is embodied in the particular fiber it traverses (Perkel and Bullock, 1968). This notion goes back to the doctrine of "specific nerve energies" of Müller (1838 and 1842; Adrian, 1928), which

DONALD H. PERKEL The RAND Corporation, Santa Monica, California and Department of Anatomy, University of California at Los Angeles, California. *Present Address:* Department of Biological Sciences, Stanford University, Stanford, California

states that the subjective quality of a sensation—the "meaning" of an afferent electrical event—depends primarily on the central connection of the nerve fiber.

Such a view of neural functioning as an analogue of a telephone system is not nearly so trivial as it might first appear. The elaboration of the labeled-line principle, as seen in the complex schemata of several neuronal organizations (Werner, this volume; Hubel and Wiesel, 1962), illustrates the pervasiveness and functional complexity of codes of this sort. Moreover, increasing evidence for the homology of neurons identifiable from individual to individual (Bullock, 1970) bespeaks a more basic role for "wired-in" neural connections than has been attributed to them.

The second kind of neural code that might be considered classical is the rate (or frequency-of-occurrence) code. It may be stated most broadly as the representation of a scalar quantity—such as stimulus intensity—by means of the rate of nerve impulses in a particular fiber or group of fibers. First clearly annunciated by Adrian (1928), it embodies a fundamental principle of neural functioning: the nerve impulses that give rise to greater and lesser sensations of intensity of a stimulus—or to greater and lesser degrees of muscle contraction—are not in themselves different; the difference lies in the number of essentially identical impulses arriving per unit of time. The operating characteristics of rate codes have been described quantitatively in terms of information capacity by Stein (1967).

In both of these "textbook" codes, little emphasis is placed on the temporal structure of the impulse train. The labeled line might carry any type of signal, and the fact that the signals are impulses is irrelevant to this concept. For a rate code, the discrete nature of the impulses appears as rather a nuisance, and fluctuations in interval lengths give rise to fluctuations in the transmitted signal, which may have to be smoothed out through time-averaging or through summation of many parallel, redundant channels. If one were to design an artificial system using the rate-code principle exclusively, it would be most efficient and reliable if, at any given signal level, impulses occurred at regular intervals (Stein, 1967).

A number of "nonclassical" codes have been proposed, however, in which other aspects of the temporal structure of the impulse train are assigned a role in the transmittal of information (Perkel and Bullock, 1968); these aspects include the standard deviation and the coefficient of variation of intervals, serial correlations of intervals, and burst characteristics, such as number of intervals, duration, and temporal pattern (e.g., accelerando or ritardando). It has, in fact, been shown that some cells are measurably sensitive to variations in several temporal characteristics, implying that such codes are indeed capable of being "read" by neurons (e.g., Wiersma and Adams, 1949; for a review, see Segundo and Perkel, 1969). The extreme example of codes that depend on temporal structure is that in which the length of each individual interspike interval carries information. The information capacity of these codes has been investigated theoretically (MacKay and McCulloch, 1952); they can handle far more bits per second than can frequency codes.

Interesting cases of "temporal-structure" spike codes are those involving more than a single channel. For reliable and rapid "reading-out" of rate codes, it is usually necessary to invoke parallel channels, but other kinds of temporal codes require several channels in a more fundamental way. Most proposed multiple-channel codes involve some elaboration of the idea of coincidence detection. In its simplest terms, a neuron may receive synaptic input from two excitatory sources, each of which alone produces a subthreshold response; if, however, the two impulses arrive within a short time interval, the neuron will be sufficiently depolarized to produce a spike. If more than two input channels are operative, and if some of the synapses are inhibitory rather than excitatory, extremely individualized "logic circuits" can be devised; these have exquisite sensitivity to slight temporal differences in arrivals.

Multiple-channel spike codes are obviously more difficult to investigate experimentally than are single-channel codes. Successful efforts in this direction have been concerned with binaural sound localization by neurons in the inferior colliculus (e.g., Rose et al., 1966). The temporal relationships between spikes in multiple, simultaneously recorded spike trains have been used for elucidating underlying functional relationships among the corresponding neurons (e.g., Gerstein, this volume), as discussed later in this article.

First, however, it is necessary to indicate that the several types of spike-train codes are not clearly separable and distinct, but rather that one tends to merge into another as characteristics of the signals or of the neurons are changed.

Rate and interval codes

Let us examine the workings of rate codes in somewhat more detail. Suppose that there is an external signal, s(t), to be represented by the firing rate of a neuron. We may think of s(t) as representing the intensity of a stimulus as it varies with time; we assume that it always has a positive value, in order to avoid irrelevant notational complications.

Suppose that a spike occurs at a time T_i ; the next spike, occurring at time T_{i+1} , defines the interspike interval, $\tau_i = T_{i+1} - T_i$, as well as the corresponding *instantaneous rate*, $\rho_i = 1/\tau_i$. A rate code is operative if the instantaneous rate, ρ_i , or its probability distribution, is determined by the history of the signal s(t), for $t \leq T_{i+1}$.

For example, the encoding unit—a receptor, perhaps may operate as an integrating device, producing a spike when the integral of the signal reaches a threshold, θ ; i.e., the time of the next spike, T_{i+1} , is determined by

$$heta = \int_{\mathrm{T}_{\mathbf{i}}}^{\mathrm{T}_{\mathbf{i}+1}} \mathrm{s}(\mathbf{t}) \mathrm{d}\mathbf{t}$$
 ,

which implies that the integrator is reset to zero after each spike.

As another example, the interval τ_i can be governed by a time-dependent Poisson process, i.e., τ_i is drawn from an exponential distribution with rate parameter $\lambda(T_i)$. The rate parameter itself may depend simply on the instantaneous signal at the time of the previous spike, e.g.,

$$\lambda(T_i) = a s(T_i) + b.$$

Alternatively, the rate parameter may represent a weighted average of the signal over some previous time period:

$$\lambda(T_i) = \int_{T_i-W}^{T_i} w(t - T_i + W) s(t) dt ,$$

or over a number, k, of preceding interspike intervals:

$$\lambda(\mathrm{T}_{i}) = \int_{\mathrm{T}_{i-k}}^{\mathrm{T}_{i}} w(t - \mathrm{T}_{i-k}) s(t) \mathrm{d}t \; .$$

If the signal varies slowly with respect to the typical times between spikes, then the operation of any of these rate codes is exemplified by Figure 1A. The regularity of the spikes will, of course, depend on the particular coding scheme operative (Stein, 1967); in a large class of cases, the timeaveraged rate of spike occurrence will closely reproduce the original signal. Now let us suppose that the signal varies rapidly with respect to the interspike intervals, but that the same encoding mechanisms are at work. Then the spike train cannot follow or reflect the rapid changes in the signal, but rather will represent a smoothed or sampled value of the signal, as seen in Figure 1B. Even if the encoder is an integrating device, the spikes will, in general, occur at irregular intervals. If a reasonable choice of weighting function, w, and of a sufficiently small value of W or k is assumed, the various types of Poisson encoders, as does the integrating encoder, will produce trains in which each interval carries information about the "local" signal level, and may be nearly or totally independent of the adjacent intervals. Here we may speak more properly of an *interval code* than of a rate code, because every interval has a meaning of its own.

The essential difference, therefore, between a rate code and an interval code does not lie in the encoding mechanism; as we have seen, any of several mechanisms may subserve either type of code. Rather, it is the relationship between the typical times of "interesting" signal variations and the interspike interval times that prescribes the nature of the code.

It follows, then, that in experimental investigations of neural codes it is important that the variations in input signal must correspond, in magnitude and time course, with those encountered under physiological conditions. The same neuron may operate with a rate code, or an interval code, or a code of intermediate type, depending entirely on

FIGURE 1 Representation of a continuous signal by a train of impulses (schematic). A: The signal varies slowly with respect to the mean interval between impulses; the representation is a "mean

rate" code. B: The signal varies rapidly with respect to interpulse interval; the representation is an "interval code." See text.

the nature of the input signal imposed. Furthermore, any quantitative estimate of information-handling capacity will depend on the input signal; a slowly varying input will yield modest information rates, as in the studies of Stein (1967), whereas a rapidly varying input to the same neuron can approach the higher information rates characteristic of an interval code (MacKay and McCulloch, 1952). We emphasize, then, that it is meaningful to talk about information capacity of a neuron or a neural pathway only within the context of a particular stimulus environment.

Statistical measures for single spike trains

The use of statistical techniques to describe the properties of spike trains has been outlined by Perkel et al. (1967a), and their application to neurophysiological problems has been reviewed by Moore et al. (1966). Here we confine ourselves to a description of only those basic statistical measures that are most useful for drawing inferences about underlying mechanisms and functional relationships.

The interval histogram is an important and widely used statistical measure of the temporal structure of a spike train. It represents an estimate of an underlying probability density function of interspike intervals. If we choose a large bin width for the histogram, the over-all profile is relatively smooth, but structural detail may be lost; if the bin width is small, detail is preserved, but individual bin tallies exhibit greater sampling fluctuations.

The interval histogram is an order-independent statistic; i.e., if intervals are randomly shuffled, the interval histogram of the reconstructed train will be identical with that of the unshuffled train.

A regularly firing neuron produces a narrow interval histogram; a "randomly" firing neuron (i.e., a Poisson process) gives rise to an interval histogram that has the form of a descending exponential function; a neuron that has exceptionally long silent periods between spikes produces an interval histogram with a long "tail"; patterned discharges, including bursts, may give rise to multimodal interval histograms.

The *autocorrelation histogram* may be thought of as the sum of histograms of intervals of all orders, i.e., intervals between adjacent spikes, between every other spike, and so on. It is also equivalent to an estimate of the likelihood (per unit time) of encountering a spike (not necessarily the nearest one) as a function of the time elapsed since the occurrence of an actual spike. The *autocorrelation density* (known also under several other names, such as renewal density and expectation density), which is estimated by the autocorrelation histogram, is defined formally as

$$\begin{split} h(\tau) &= \lim_{\Delta t \to 0} \left[(1/\Delta t) \operatorname{Prob} \left\{ \text{spike in} \left(t_0 + \tau \right. \right. \right. \\ & \left. t_0 + \tau + \Delta t \right) \right] \\ & \left. t_0 + \tau + \Delta t \right] \\ \end{split}$$

For a Poisson process, the autocorrelation density is flat. Neurons that fire at fairly regular intervals, such as pacemaker cells, give rise to an autocorrelation histogram that displays regularly spaced peaks and valleys, which flatten out progressively. For essentially all neurons, the autocorrelation density approaches a constant asymptotic value for sufficiently large values of its argument. This reflects the fact that knowing the time of occurrence of one spike enables us to predict the future likelihood of encountering other spikes in that train, but that this predictive power does not extend indefinitely into the future (barring the theoretical case of a "perfect" clock). Eventually, the time of occurrence of the original spike is "forgotten," and the likelihood of a spike is determined only by the over-all mean firing rate. For a Poisson process-completely "random" firingthe forgetting takes place immediately.

All neurons, because of refractory effects, display an initial zero autocorrelation, followed by a steeply rising portion. In certain neurons, this refractory effect, shown in the early bins of the autocorrelation histogram, is all that distinguishes the spike train from a true Poisson process.

The autocorrelation histogram reflects, in a complex fashion, the presence of serial dependencies among interspike intervals. If the intervals are shuffled at random, the autocorrelation histogram of the reconstructed train will remain essentially the same only if successive interval lengths are independent. If they are not, the two autocorrelation histograms will differ; the peaks may become sharper or broader, depending on the nature of the serial dependencies.

A more sensitive statistical measure of the serial dependencies of interval lengths is the *serial correlogram*. This is the set of serial correlation coefficients $\gamma_1, \gamma_2, \gamma_3, \cdots$, defined by

$$\gamma_{i} = \sigma^{-2} E(T_{i} - \mu)(T_{i+1} - \mu)$$
,

in which μ and σ are the mean and standard deviation of interval length, respectively. In other words, the serial correlation coefficient of order j is the expected value of the product of the (normalized) interval length with that of the j'th following interval length. For example, the first-order serial correlation coefficient, γ_1 , measures the serial dependence between each interval and its immediately following one. A value of γ_1 close to unity means that relatively short intervals are nearly always followed by short ones, and long ones by long ones. A value of γ_1 close to -1 indicates that short intervals are highly likely to be followed by long ones, and vice versa. A value close to zero indicates that successive interval lengths are uncorrelated (although it does not necessarily imply that they are independent).

A usual contribution to nonzero serial correlation coefficients is that of trends or relatively slow rate changes in the experimental record. Either a long-term slowing-down or speeding-up of the firing rate during the observation will produce positive serial correlations for high as well as low orders. More rapidly changing rates produce positive serial correlations of the lower orders, which then typically become negative before returning to zero. Bursts and patterned discharges typically show more rapid oscillations in the earlier portions of the serial correlogram.

Shuffling the intervals in the spike train destroys all serial dependence. The serial correlogram of the shuffled train represents a control case, the fluctuations of which around zero reflect solely sampling variations.

The serial correlation coefficient was used in one of the earliest examples of statistical analysis of single spike trains (Hagiwara, 1950). Hagiwara observed that the first-order serial correlation coefficient (in the muscle-spindle afferent fiber) was equal to -0.5, and that the serial correlation coefficients of higher order were all very close to zero. It is easily shown (McGill, 1962) that, if the impulses arising from a regular clock are subjected to independent random delays (with the provision that the variations are not so great as to destroy the serial order of the impulses), the train of delayed impulses will have serial correlation coefficients equal to $-0.5, 0, 0, \cdots$. Hagiwara interpreted this serial correlogram as being consistent with an extremely regular source of impulses transmitted over pathways that produced random delays before the impulses reached the recording site. In this case, the existence and certain properties of an unobserved unit were inferred from statistics of a spike train observed in another unit.

Other statistical analyses of single trains have yielded insights concerning intracellular mechanisms. For example, the analysis of interval fluctuations in pacemaker neurons of *Aplysia* by Junge and Moore (1966), aided by computer simulations, pinpointed the most likely source of the fluctuations as the asymptotic level of the pacemaker potential, in turn attributable to irregular shifts of the spike-initiating locus. Further examples of the interpretation of single-train statistical analyses were given by Moore et al. (1966) and by Harmon and Lewis (1966).

It is in the analysis of several spike trains observed simultaneously, however, that the strongest inferences can be made about underlying mechanisms.

Comparison of simultaneously observed spike trains

The principal statistical tool for the comparison of two simultaneously observed spike trains is the cross-correlation histogram (Perkel et al., 1967b). It is defined and used in a fashion analogous to that of the autocorrelation histogram, and represents an estimate of the density

$$\begin{aligned} k_{AB}(\tau) &= \lim \left[(1/\Delta t) \operatorname{Prob} \left\{ \text{spike in B in} \left(t_0 + \tau \right. \right. \right. \\ \Delta t \to 0 \\ & t_0 + \tau + \Delta t \right) \left| \text{spike in A at } t_0 \right\} \right]. \end{aligned}$$

If two neurons are functionally independent, the cross-

correlation histogram is flat, to within sampling fluctuations only. We have proposed that the flatness of the cross-correlation histogram be used as a criterion of functional independence between two neurons during the period of observation (Moore et al., 1966).

Various types of functional relationships between the monitored neurons give rise to characteristic "signatures" in the cross-correlation histogram, as described in detail by Moore et al. (1970). The material presented in this section is drawn from that paper. By observing features in the crosscorrelation histogram, one can, in some cases, infer the underlying functional relationships and estimate some of the relevant parameters; in other, less favorable cases, it is still possible to narrow the choice of admissible hypotheses about the underlying neurons.

If spike trains A and B are recorded from presynaptic and postsynaptic members of a pair of neurons, respectively, several features are observable in the cross-correlation histogram (Figure 2). The primary effect is a peak or valley, situated to the right of, and close to, the origin. A peak is observed if the synapse is excitatory; a valley, if it is inhibitory. If the inhibition is strong enough, firing may be suppressed completely for a time, as indicated by a drop in the crosscorrelation histogram to zero. When not obscured by secondary effects (described below), and when well revealed by a sufficiently long sample and a fine enough bin width in the histogram, the primary peak reflects the time course of the typical postsynaptic potential induced in neuron B. Although the mapping is in general not precisely linear, it nevertheless enables the making of useful estimates of such parameters as the rise and fall times of the postsynaptic potential. The displacement of the primary peak or valley to the right of the origin reflects the over-all delay between the recording of the presynaptic impulse by the first electrode and the postsynaptic impulse by the second.

In addition to the primary effect, a number of secondary effects arise, owing to rhythmicities and refractory effects in the two neurons, i.e., departures from flatness in the respective autocorrelation histograms.

The *presynaptic* autocorrelation is mapped bilaterally and symmetrically around the peak or valley representing the primary effect. It has the same sign as the primary effect, so that if the synapse is excitatory, peaks in the presynaptic autocorrelation give rise to peaks in the cross correlation; if the synapse is inhibitory, peaks in the presynaptic autocorrelation give rise to valleys in the cross correlation. The peaks and valleys are broadened to an extent that corresponds to the effective width of the postsynaptic potential, or to that of the primary peak or valley.

Postsynaptic rhythmicities and other features of the autocorrelation of train B are mapped unilaterally, to the right of the primary peak or valley. Again, the sign of the primary peak is preserved: peaks in the postsynaptic autocorrelation correspond to peaks in the cross correlation if the synapse is excitatory; and to valleys, if it is inhibitory. The intensity with which these rhythmicities are mapped depends on the extent to which the presynaptic impulses reset the rhythm of the postsynaptic cell. If the latter is not an autonomous pacemaker, but rather is driven by a third, independent pacemaker neuron, the rhythmicity shown in the oscillations of the autocorrelation histogram of cell B will not be reflected in the AB cross-correlation histogram. From such an observation, it is possible to infer the existence of the unobserved driver neuron.

Combinations of these effects can result in a complex structure of the cross correlation, even in this simplest case of a trans-synaptic pair. Unraveling the several effects appears to be most readily accomplished through the techniques of spectral analysis, described in the concluding section of this article.

If cell B is the presynaptic element and cell A the postsynaptic member of the pair, the preceding effects are still present, *mutatis mutandi*, e.g., the primary peak and the postsynaptic secondary effects will appear to the left of the origin in the cross-correlation histogram.

Another basic configuration is that in which the two monitored neurons, A and B, have no synaptic connections between them, but rather receive synaptic input from a common source, C, either directly or through interneurons. The observable features in the cross-correlation histogram between A and B are rather more complex than the transsynaptic case outlined above (Figure 3): the *primary effect* occurs in general on both sides of the origin; it may be dis-

C: One slightly irregularly firing pacemaker excites a more irregularly firing pacemaker. The secondary peaks to the left of the arrow reflect the autocorrelation of the presynaptic cell; those to the right of the arrow include features of the autocorrelations of both cells. See text. placed to the right if the conduction time from C to A is shorter than that from C to B, or to the left if the converse is true. It will be centered about the origin if the conduction times are about equal.

If the synapses on A and B are both excitatory or both inhibitory, the primary effect consists of a rather broad, symmetrical peak. If one synapse is excitatory and the other inhibitory, the shape will involve a valley and a peak; the precise configuration depends on the shapes and amplitudes of the two postsynaptic potentials, as well as on the relative times of arrival. A cross-correlation histogram of Rodieck (1967, Figure 10B) appears to be consistent with this class of underlying configuration; for a fuller discussion, see Moore et al. (1970).

stimulus train and second neuron. C: Cross-correlation histogram between the two neurons. Peak is more symmetrical and centrally placed than in upper examples. D: Computer-simulated neurons. Cross-correlation histogram between two neurons excited by a common rhythmic "driver"; arbitrary time scale. See text; for further examples see Moore et al. (1970). The secondary effects include the autocorrelations of all three neurons. That of the common source, C, is reflected symmetrically and bilaterally around the peak (or other feature) representing the primary effect. The autocorrelation of cell A is mapped unilaterally to the left of the primary peak; that of cell B is mapped unilaterally to the right of the primary peak. In addition, a complicated admixture of the autocorrelations of A and B will be mapped on both sides of the primary peak. The more conspicuous of these effects are illustrated in Figure 3.

In addition to synaptic effects, shared rate changes can elevate or depress the cross-correlation histogram (Perkel et al., 1967b). Typically, the time scales of shared rate changes are much longer than those of synaptic effects, so that the two can readily be distinguished. The cross-correlation histograms of Holmes and Houchin (1966) between widely separated cortical units appear to arise from a shared rhythmicity attributable to a common activating mechanism.

Recent examples of cross-correlation histograms, interpreted in terms of the underlying functional anatomy, appeared in the papers of Noda et al. (1969) and of Bell and Grimm (1969).

The enormous tangle of primary, secondary, and perhaps also tertiary effects in even the simplest anatomical configurations makes it difficult to infer neuronal connections directly from correlational analysis of spike trains. However, two additional approaches have genuine promise in this area. The first approach is to apply a periodic stimulus to the preparation, while monitoring two or more spike trains. The statistical analysis and interpretation of the results of experiments of this kind are discussed by Gerstein (this volume).

The other approach is the use of spectral analysis, according to the notions briefly sketched in the remainder of this article.

Spectral analysis of spike trains

In place of the autocorrelation and cross-correlation histograms discussed above, which are in the time domain, the spectral analysis of spike trains makes use of the autospectrogram and cross-spectrogram, in the frequency domain. The autospectrogram is an estimate, from an experimental sample, of an autospectrum, or autospectral density, which is defined as the Fourier transform of the autocovariance of the spike train. Similarly, the cross-spectrum, or crossspectral density, is the Fourier transform of the cross covariance.

The autocovariance is related simply to the autocorrelation density (or renewal density) of a spike train: one adds a delta function at the origin, subtracts the mean rate, and multiplies by the mean rate, to yield the *complete autocovariance*:

$$\zeta'(\tau) = \rho[h(\tau) + \delta(\tau) - \rho].$$

Eliminating the delta function gives the *incomplete autoco-variance*:

$$\zeta(\tau) = \zeta'(\tau) - \rho \delta(\tau) = \rho[h(\tau) - \rho].$$

The delta function is introduced to reflect the fact that every spike is in coincidence with itself.

A right-hand autocovariance is defined by

$$\eta(\tau) = \begin{cases} \zeta(\tau) & \tau > 0\\ 0 & \tau \le 0 \end{cases}$$

The cross covariance is obtained from the cross-correlation density simply by subtracting the mean rate of the second train, and then multiplying by the mean rate of the first train:

$$\xi_{ij}(\tau) = \rho_i[k_{ij}(\tau) - \rho_j].$$

The cross covariance between a train and itself is simply the complete autocovariance:

$$\xi_{\mathrm{i}\mathrm{i}}(au) = \zeta_{\mathrm{i}}'(au) =
ho_{\mathrm{i}}\delta(au) + \zeta_{\mathrm{i}}(au) \,.$$

The autocovariance is an even function:

$$\zeta(-\tau)=\zeta(\tau)$$

and the cross covariance between two trains taken in reverse order is simply the mirror image of the original cross covariance:

$$\xi_{ji}(\tau) = \xi_{ij}(-\tau)$$

The Fourier transform of any function, $f(\tau)$, is defined as follows:

$$f^{*}(\omega) = T[f(\tau)] = \int_{-\infty}^{\infty} e^{-i\omega t} f(t) dt$$
$$= \int_{-\infty}^{\infty} [\cos \omega t - i \sin \omega t] f(t) dt$$

If the function $f(\tau)$ in the time domain is even, its Fourier transform is real; otherwise, it is complex. The Fourier transform may be inverted to yield the original time-domain function:

$$f(au) = rac{1}{2\pi} \int_{-\infty}^{\infty} e^{i\omega au} f^*(\omega) \, \mathrm{d}\omega \; .$$

The Fourier transform is a linear operator, and has the very useful convolution property which states that, if

 $h(t) = \int_{-\infty}^{\infty} f(t-z)g(z) dz ,$

then

$$h^*(\omega) = f^*(\omega)g^*(\omega) ;$$

that is, the Fourier transform of the convolution integral of two functions is the product of their individual transforms.

594 COMMUNICATION AND CODING IN THE NERVOUS SYSTEM

The properties of Fourier transforms in general are given in many standard texts, e.g., Brown (1965) and Jenkins and Watts (1968). The spectral analysis of point events was described by Bartlett (1963) and by Cox and Lewis (1966).

The fundamental application of the Fourier-transform approach to spike-train analysis lies in the following situation: we may express the cross covariance measured between a presynaptic and a postsynaptic location by means of a convolution equation between the presynaptic autocovariance and a function, ϵ (τ), which we call the synaptic response:

Upon taking Fourier transforms, we express the cross spectrum as the product of the presynaptic autospectrum and the transform of the synaptic response:

$$\xi_{jk}^{*}(\omega) = \xi_{jj}^{*}(\omega)\epsilon^{*}(\omega) .$$

The foregoing equations define the function $\epsilon(\tau)$; it always exists in any steady-state situation, and can be estimated by dividing

$$\epsilon^*(\omega) = \xi^*_{jk}(\omega)/\xi^*_{jj}(\omega)$$

and then inverting the Fourier transform. When a linear system is dealt with, the function analogous to $\epsilon^*(\omega)$ is known as the transfer function, and it does not change when the input is changed. In the (nonlinear) system under discussion (presynaptic and postsynaptic spike trains) the question of the dependence of the function $\epsilon(\tau)$ on the nature of the input train is an empirical one, which is under investigation in both living and simulated preparations.

The convolution equations above describe the presynaptic secondary effect on the cross-correlation histogram: the bilateral mapping of the presynaptic autocorrelation. The primary effect and the postsynaptic secondary effect arise on further analysis of the synaptic response function, as follows:

$$\epsilon(\tau) = \sigma(\tau) + \kappa \int_{0}^{\infty} \eta(\tau - z)\sigma(z) dz$$
$$\epsilon^{*}(\omega) = \sigma^{*}(\omega) \left[1 + \kappa \eta^{*}(\omega)\right]$$

in which the first term, $\sigma(\tau)$, may be designated the *primary* response, and the term containing the convolution integral may be designated the secondary response. The function $\eta(x)$ is the one-sided autocovariance (of the postsynaptic discharge), as defined previously, and κ is a scalar coefficient; it reflects the extent to which the postsynaptic cell's rhythmicity is reset by presynaptic impulses.

The primary response, $\sigma(\tau)$, describes the mapping of the postsynaptic potential. It can be recovered, once $\epsilon^*(\omega)$ has

been estimated, by assuming several values for κ , dividing, and inverting.

Thus, the spectral formalism not only describes quantitatively all the qualitative features of the trans-synaptic cross correlation, but also furnishes a means whereby the primary synaptic response can be disentangled from confusing secondary effects. That is, numerical processing of spiketrain data can yield an estimate of the time course of the effect of the postsynaptic potential on the firing probability of the postsynaptic neuron.

We can systematically apply the same techniques to the case of shared synaptic input, using some of the symmetry properties of the Fourier transform, to yield a final expression for the cross spectrum as follows:

in which the expressions $\alpha^*(\omega)$ refer to the Fourier transforms of the conduction delays (constant or randomly fluctuating) between the points indicated by the subscripts.

By expanding the last two factors in the above expression, we can show how it accounts for all the qualitative properties we have described previously:

$$\begin{split} \epsilon_{2}^{*}(-\omega)\epsilon_{3}^{*}(\omega) \\ &= \sigma_{A}^{*}(-\omega)[1+\kappa_{A}\eta_{A}^{*}(-\omega)]\sigma_{B}^{*}(\omega)[1+\kappa_{B}\eta_{B}(\omega)] \\ &= \sigma_{A}^{*}(-\omega)\sigma_{B}^{*}(\omega)[1+\kappa_{A}\eta_{A}^{*}(-\omega)+\kappa_{B}\eta_{B}^{*}(\omega) \\ &+\kappa_{A}\kappa_{B}\eta_{A}^{*}(-\omega)\eta_{B}^{*}(\omega)] \,. \end{split}$$

The first term in this expression represents the "primary response" in the shared-input case. Note that if both synapses are excitatory, or if both are inhibitory, the first term will be positive, as will be the corresponding feature in the cross covariance. This is in agreement with the observed finding that both shared excitation and shared inhibition give rise to a central peak in the cross-correlation histogram, whereas a central valley and peak of more complicated form arise from a common source that is excitatory to one observed neuron and inhibitory to the other.

The second term reflects a unilateral mapping of the autocovariance of neuron A to the *left* of the central primary response; the third term reflects the corresponding unilateral mapping of the autocovariance of neuron B to the *right* of the central response. The fourth term represents a more diffuse mixture (i.e., a difference convolution) of the two unilateral covariances, reflected in the cross covariance on both sides of the central peak or valley.

Note also that if the previous equation held, and if we knew or could satisfactorily estimate the coupling coeffi-
cients κ_A and κ_B , we could solve for

$$[
ho_{
m C}+\zeta_{
m C}^{*}(\omega)]lpha_{12}^{*}(-\omega)lpha_{13}^{*}(\omega)\sigma_{
m A}^{*}(-\omega)\sigma_{
m B}^{*}(\omega)$$

which gives the autospectrum of the unobserved common source, convolved with the difference of the conduction times and with the two primary synaptic responses with appropriate sign.

It can be shown, in addition, that the technique illustrated above can be extended to arbitrary networks of neurons, so that we can prescribe a generally applicable set of rules for expressing the cross spectrum between any two points in a loopfree network in terms of the delays and synaptic properties of the intervening pathways, together with the rhythmicities of injected sources of impulses. Loops in the network yield homogeneous equations, leading to the hope that statistical criteria can be developed for detecting and characterizing loops on the basis of spike data.

With the exception of the work of Terzuolo and his group (this volume), the technique of spectral analysis of series of point events (Cox and Lewis, 1966) has seldom been applied to neuronal spike data. Its application to simultaneously observed spike trains is under active investigation at the time of writing (Perkel and Segundo, 1969). The technique holds the promise of being able to provide quantitative answers to certain problems raised by the timedomain statistics of spike trains, and thereby to provide additional information about underlying structures and about the ways nerve cells communicate with one another.

53 The Role of Spike Trains in Transmitting and Distorting Sensory Signals

R. B. STEIN

IN RECENT YEARS there has been a tremendous growth of statistical techniques for analyzing the patterns of nerve impulses generated by single cells. This has led to greater insight into the detailed mechanisms of neuronal activity, but to what extent has it increased our understanding of the function of nerve cells in transmitting information? Can the ability of nerve cells to convey information from one part of the nervous system to another by means of spike trains be assessed accurately? If so, what parameters of the train convey information and how well do they convey it? Conversely, what types of signals will be distorted and how badly? Before considering these questions, let us examine an underlying assumption—that information is coded in the form of trains of all-or-none nerve impulses, rather than analogue parameters of the membrane potential.

Rushton (1961) argued strongly in favor of a code employing impulse trains by pointing out that the space constant of nerve fibers is short. The space constant λ is the distance over which the voltage produced by a steady point source of current applied to a linear, cable-like nerve fiber will decay to 1/e of its value at the point of application. Hodgkin and Rushton (1946) showed that

$$\lambda = \sqrt{g_a/g_m}, \qquad (1)$$

in which g_m is the membrane conductance and g_a the axoplasmic conductance of a unit length of cable. Because the axoplasm must inevitably contain a dilute salt solution, g_a must be low and therefore λ must be small. In a long length of nerve, the signal must be boosted repeatedly, and in myelinated nerve, the nodes of Ranvier can be thought of as just such boosters. Because there may be hundreds of nodes between a sense organ and the central nervous system, accurate transmission of an analogue signal would be extremely difficult. The boosters would have to be made of very high-tolerance components if the analogue signal at the end is to bear any relation at all to that at the beginning. Experimental evidence for sufficiently high tolerance components was lacking, so Rushton concluded that little information could be transmitted in this way.

Rushton's argument is certainly true for much of the nervous system, but it has important limitations. It applies only to fiber tracts that are long enough to contain a number of nodes of Ranvier. Evidence is accumulating that cells in the central nervous system (Shepherd, this volume; Rall, this volume), and in the retina (Werblin and Dowling, 1969) that have only short processes may use analogue signals in addition to or in place of nerve impulses. Rushton's argument also applies with less force to large axons. The values of g_m and g_a are conductances per unit length of cable, and with a cable of diameter d, these quantities can be quickly converted to more basic ones which vary much less from axon to axon. Let G_m be the membrane conductance per unit area of membrane and Ga the axoplasmic conductivity. Then geometric considerations indicate that $g_m = \prod d G_m$, and $g_a = \prod d^2 G_a/4$, so the length constant

$$\lambda = \sqrt{\frac{d G_a}{4 G_m}} \tag{2}$$

increases as the square root of fiber diameter. Corresponding arguments for myelinated nerve (Rushton, 1951; Noble and Stein, 1966) indicate that the characteristic length of myelinated fibers increases linearly with diameter, so the advantages of size are more marked.

In agreement with the idea that nerve impulses may be less important in large fibers, recent experimental work indicates that some large invertebrate sensory axons do not use nerve impulses at all. Bush and Roberts (1968) studied muscle receptors in the walking legs of the crab. Those receptors supply two sensory fibers, each of which is about 50 microns in diameter and several millimeters in length. During stretch of the muscles, intracellular and extracellular records show only graded responses. The fibers were not unduly damaged by the insertion of microelectrodes, because simultaneous records from motor axons indicated that the graded responses were capable of producing reflex effects. Furthermore, electrical stimulation also produced only graded responses, but nonetheless had reflex effects. Thus, some sensory fibers may use analogue signals exclusively, but their limitations in transmitting information should be recognized. Not only must the fibers be of large diameter and fairly short; their frequency response would probably be very limited if the effects were purely passive. The trans-

R. B. STEIN Department of Physiology, University of Alberta. Edmonton, Alberta, Canada

fer function L(s) for linear cable with time constant τ and space constant λ is (Stein, 1967, equation 2.33)

$$L(s) \propto \exp(-\sqrt{1+s\tau} x/\lambda)/\sqrt{1+s\tau}$$
 (3)

Thus, the decline as a function of distance for signals with a frequency component s is much sharper than that of a steady signal. From equation (3) the steady-state response, $e^{-x/\lambda}$, is raised to the $\sqrt{1 + s\tau}$ power and divided by $\sqrt{1 + s\tau}$ for signals with a frequency component s. This very sharp frequency cutoff means that only slowly changing signals can be transmitted considerable distances in a linear cable. Rall (1962) has presented similar arguments based on the particular geometry of dendritic structures, indicating that distal dendrites probably act to produce a nearly steady bias level at the cell body of a motor neuron. Thus, information transfer, particularly about rapidly varying signals over considerable distances, must take place mainly by means of all-ornone nerve impulses.

Even if nerve impulses were strictly all-or-none, there is no insurance that each nerve impulse in a train will have identical effects synaptically. The effect of one impulse in potentiating or depressing the release of transmitter by a subsequent impulse is well known, and presumably very important in the adaptive behavior of the nervous system. Such a situation is basically different, however, from that of a signal based on analogue parameters of the membrane potential, and merely indicates that the device receiving the signal weights more or less strongly nerve impulses that take place at certain intervals. This weighting clearly affects input-output relationships, but the response of the next cell still depends entirely on the times of occurrence of nerve impulses. In other words, the discharge pattern of a nerve cell represents a statistical point process, and the information conveyed by the nerve cell is in terms of parameters of this process. Let us now consider what parameters are important in such a process.

The number of nerve impulses over a period of time or impulse frequency is clearly an important parameter, as Adrian and Zotterman (1926) first noted from their records of single sensory fibers. Increasing the sensory stimulus increased the frequency of nerve impulses smoothly, and this property is often referred to as frequency coding or frequency modulation of a sensory stimulus. If the steady discharge produced by a constant stimulus is either completely regular or completely random (Poisson process), then the mean is the only parameter available to convey information. In intermediate examples, or with time-varying stimuli, other parameters may convey information, but first let us analyze the amount of information that can be conveyed by mean rate alone. This requires some ideas from the mathematical theory of communication, which I have developed in detail elsewhere (Stein, 1967b).

Information transmission by constant signals

Consider a discrete series of sensory stimuli, each lasting a time t and repeated at a suitable repetition rate. Figure 1 shows schematically a single stimulus trial applied to a nerve cell discharging with a steady rate ν_{min} prior to stimulation. The stimulus of duration t increases the frequency and produces x impulses on average. This variable x is often considered as the neuronal response, but is treated here as the input to a communications channel, because the average frequency or mean number of nerve impulses may be the only quantity wholly determined by the stimulus. The response variable y is the number of nerve impulses actually discharged on a single trial. It will vary from trial to trial because of random fluctuations in the part of the cycle at which the stimulus begins, because of fluctuations in the duration of successive interspike intervals, and a number of other factors that can be lumped together under the heading of the "state" of the neuron.

These sources of variability limit the information that the nervous system (or the experimenter) can obtain about the stimulus from knowing the number of nerve impulses discharged on a single trial. The amount of information depends on three probability density functions: p(x), the probability that the stimulus on a particular trial is x; p(y), the probability that the response is y; and, most important of all, p(y/x), the conditional probability that the response is y, given that the stimulus is x. Only two of these three functions are independent. If the stimulus probability function p(y/x) are known for all x, the response probability function p(y/x) alone determines the properties of a neuron as a communi-

FIGURE 1 An idealized spike train and its analysis in terms of the probabilities of variables associated with a communications channel. Further explanation in text.

cations channel. From this function, the maximum amount of information a neuron could transmit about steady signals can be calculated, together with the stimulus distribution necessary to achieve this maximum. The amount of information, I, can be thought of as the logarithm of a number M which represents the maximum number of discriminable categories with the use of an optimal stimulus distribution. Logarithms to the base 2 are normally used, so

$$I=\log_2 M,$$

and the units of I are then denoted by the term binary bits of information. In general, to obtain I directly is tedious, but some simplifications result when there are substantial numbers of nerve impulses, either from a single neuron or a population. Then, the amount of information, I, available from a single stimulus trial can be calculated by means of the equation (Stein, 1967b, equation 2.9)

$$I \sim \log \begin{bmatrix} x_{max} \\ \int \\ x_{min} \frac{dx}{\sqrt{2\Pi e} s(x)} \end{bmatrix}.$$
 (4)

I shall not attempt to derive this equation here, but simply note that the information and, hence, the number of discriminable categories M depends on two quantities—the range in the mean number of nerve impulses that can be produced by stimulation, $x_{max} - x_{min}$, and s(x), which is the standard deviation in the number of impulses produced from trial to trial when the mean number is x. If the discharge pattern behaves as a renewal process (i.e., each interspike interval is independent of every other one), with a mean interval μ and a standard deviation σ , then the mean number of impulses in time t approaches t/μ and the standard deviation in number approaches

$$s(x) \sim \sigma \sqrt{t/\mu^{3/2}} \,. \tag{5}$$

Equation (5) is the product of two factors, the coefficient of variation σ/μ for a single interval and the square root of the mean number $\sqrt{t/\mu}$. If equation (5) be substituted into equation (4), it follows that

$$I \sim \log\left[\sqrt{\frac{t}{2\Pi e}} \int_{\mu 0}^{\mu 1} \frac{d\mu}{\sigma \sqrt{\mu}}\right],\tag{6}$$

in which μ_0 and μ_1 are the minimum and maximum mean interspike intervals that a sensory stimulus of duration t can produce. The standard deviation, σ , of the interval distribution is considered as a function of the mean, μ . Equations can also be derived (Stein, 1967b) for single nerve cells, the discharge of which shows serial dependencies, and this analysis can be extended to a functionally similar group of cells whose individual properties are known. The parameters required are all readily measurable with present techniques, and the maximum number of discriminable stimulus categories can be estimated from, for example, a discharge of one second. Values obtained either by using the equations above or by direct measurement of the probability functions required are now available for a number of sensory receptors and have been collected in Table I.

These values represent the maximum amount of information that can be obtained about a constant stimulus, with trials lasting about one second. Grüsser (1962) suggested much higher values (nearly 100 bits) but neglected neuronal variability, which greatly restricts transmission of information. Theoretically, an even greater capacity for information

 TABLE I

 Ability of some sensory fibers in the cat to transmit information about steady signals

transmission in one second would be possible by use of time-varying stimuli and a form of binary coding or interval coding (Mackay and McCulloch, 1952; Rapoport and Horvath, 1960; Färber, 1968), although these ideas have not been tested experimentally. In a binary code, time is divided into discrete periods, and in each period a pulse is either present or absent (one bit of information). A single nerve cell may discharge as many as 1000 impulses a second, so nearly 1000 bits per second would be transmitted in this way. Adjacent fibers might further increase the rate by transmitting independent information in much the way a paper tape or card reader utilizes a number of channels in parallel. By continuously grading the interspike intervals, rather than using discrete intervals of time, one could obtain even higher rates.

Figure 2 shows a comparison of information rates with the use of these various codes. They diverge widely for long times, because with steady inputs the information transmitted by a frequency code increases as the logarithm of time, rather than linearly. Mackay and McCulloch (1952) did not assume that a nerve cell used either a pulse or an interval code, although later workers (Rapoport and Horvath, 1960; Färber, 1968) were less explicit on this point. Nonetheless, for steady signals, these higher estimates are clearly unrealistic, as no neural mechanisms known could encode a steady signal as a series of binary coded digits or coded intervals. Nor are mechanisms known for decoding such signals centrally. Finally, the presence of neuronal variability would severely limit the operation of such a system, which depends either on a high degree of reliability or on elaborate error-checking procedures. Even the estimates for information as a function of time with the use of a frequency code may be too high. The amount of information available about a steady signal will ultimately be limited by slow background changes, which affect the mean rate of discharge of the signal neuron or group of neurons considered.

The values in Table I are in general agreement with psychological measurements, which indicate that only about seven categories in a single stimulus dimension can be discriminated by human subjects (Miller, 1956) and that the maximal rate of information transmission is less than 100 bits per second (Quastler, 1956). Further verification of this analysis must await comparison of behavioral and neurophysiological experiments carried out at several levels of the nervous system under closely controlled conditions (see, for example, Talbot et al., 1968).

The analysis up to this point has a number of weaknesses that should be explored further:

1. Only maintained stimuli that produce constant responses have been considered, whereas the nervous system appears to be more interested in change (Barlow, 1961).

2. Only the nerve impulses in a clearly defined period

have been counted. The response of a real nerve cell will not be limited to any period in time, but will be an ongoing process that reflects recent presynaptic impulses more strongly. An exponential rather than a rectangular weighting of impulses would be more appropriate.

3. Parameters other than the mean number of spikes in a given period have been neglected. In particular, the role of neuronal variability remains obscure.

Time-varying signals

A different approach has been used to overcome these problems. Consider now the response of a nerve cell to a smoothly varying sinusoidal stimulus, again assuming that the number of impulses per unit time is the appropriate output variable. If this assumption is valid, the response of the nerve cell can be measured with the use of a poststimulus time histogram, in which each sweep of the histogram is triggered at a particular phase of the sine wave. Then each bin contains the number of impulses occurring at some phase of the sine wave within a time determined by the bin width and the number of sweeps. The units can be easily converted to impulses per second, and the values in each bin give a measure of the expected density of nerve impulses at a particular time after the start of the sine wave. The impulse density may be measured over a period that is short compared with single interspike intervals, and, although the units are the same, it should be distinguished from an average frequency measured over a long period of time. This technique has been applied to a variety of sensory

FIGURE 2 Information transmitted as a function of stimulus duration for an idealized neuron (A) discharging randomly and using a frequency code, (B) discharging fairly regularly and using a frequency code, (C) using a binary pulse code, and (D) using an interval code.

systems (Kiang, 1965; Talbot et al., 1968; Matthews and Stein, 1969a) and has recently been simulated by use of electronic neural analogues (French and Stein, 1970). These studies indicate that neuronal variability, far from limiting information transmission with time-varying stimuli, may actually permit more accurate transmission of the details of such stimuli.

Figures 3 and 4 illustrate the results using the neural analogue. Nerve cells that discharge regularly often become phase locked to a sinusoidal stimulus. Figure 3 shows simulation of this behavior, in which a 67-Hz sine wave was applied to a neural analogue that was producing 100 pulses per second in the absence of stimulation. This Figure represents the superposition of several sweeps, so the response is strictly locked to the stimulus, with three pulses occurring every two cycles. Pulses take place only at those three times in the cycle, so the poststimulus time histogram (Figure 4A) has three sharp peaks and is obviously a very distorted version of the sine wave stimulus. Increasing amounts of white Gaussian noise, however, added as an additional input to the analogue, will disrupt the strict timing of the responses (Figure 4B), and eventually (Figure 4C, D) the impulse density shows a smooth sinusoidal variation. The dots give the best-fitting sinusoidal curve to the data in the sense of minimum-square deviation from the data points. The amount of noise required to disrupt these phase-locked patterns clearly depends on the amplitude and frequency of the applied sinusoid. Figure 5 shows the frequency response of the neural analogue at a number of noise levels. The frequency in the absence of stimulation was again 100 pulses per second, and the amplitude of the stimulus was kept constant at a value which produced a modulation at low cyclic frequencies of just under 20 pulses per second. The amplitude of the response in the

FIGURE 3 A neural analogue discharging at 100 pulses per second was stimulated by a 67-Hz sine wave as shown in the bottom trace. The resultant voltage changes in a "leaky" integrator with a time constant of 10 milliseconds are shown in the middle trace. The output pulses shown in the top trace are produced each time a threshold level (1V) is exceeded and they reset the integrator. This Figure represents several sweeps which superimposed exactly, with three pulses occurring for every two cycles of the applied sinusoid.

absence of noise (Figure 5A) has obvious peaks at 50, 100, 200 Hz, and so on. These peaks and the corresponding effects on the phase of the response (B) represent distortions caused by the phase locking of the response to sine waves of these frequencies. These distortions are progressively reduced with increasing noise levels (Figure 5C, D), although at high noise levels the frequency response of the system begins to decline (Figure 5E, F). Also, the mean-square deviation of the best-fitting curve derived from the data obtained by averaging a given number of sweeps eventually begins to increase again at high noise levels. For a given range of stimulus frequencies and amplitudes, an optimal level of neuronal variability will exist that permits efficient transmission of information with only a small amount of distortion. In general, this optimal level will be greater the larger the amplitude of the stimuli and the closer the stimulus frequencies are to the discharge rate of the cells in the absence of stimulation or small multiples of this rate.

This argument suggests that cells responding to rapidly changing stimuli would require a higher level of variability to operate efficiently than those responding to slowly changing or static stimuli. Consideration of experimental data from various mechanoreceptors in the cat tends to confirm this idea. Those that respond to the most rapidly changing stimuli, e.g., cochlear neurons (Kiang, 1965) and fast-adapting receptors in the foot pad (Armett et al., 1962), discharge with extreme variability, whereas those that adapt slowly and respond to maintained stimuli, e.g., muscle spindle afferents (Matthews and Stein, 1969b) and slowly adapting skin afferents (Werner and Mountcastle, 1965), discharge with great regularity. Even between primary and secondary muscle-spindle afferent endings (Matthews and Stein, 1969b) and Type I and Type II slowly adapting cutaneous afferents (Chambers and Iggo, 1967), the more slowly adapting types-in the sense that they have a relatively smaller dynamic sensitivity-also discharge more regularly under a variety of conditions.

Spatial averaging

There is still a weakness in this analysis, because it is based on long-time averages from single nerve cells or neural analogues. The response of higher-order neurons is presumably based on an average over the large number of fibers that make synaptic contact with it in a limited period of time. However, there is a class of statistical processes known as *ergodic* processes, in which an average over nrecords of duration t is equivalent to a single longer record of length nt. To prove that a population of nerve cells represents a single ergodic process, it must be shown that (1) the parameters necessary to specify the discharge of each cell are identical; (2) the discharge of the cells during maintained stimulation are uncorrelated; and (3) the time t is

в

FIGURE 4 Poststimulus time histograms for the response of a neural analogue to the sinusoid shown in Figure 3, with increasing amounts of noise added (A-D). The extent of the histogram represents exactly one full cycle of the applied sinusoid, and each sweep was begun so that the peak of the applied sine wave came in the middle of the histogram. The ordinate has been converted to pulses per second by divid-

ing the number of pulses in each bin by the bin width and the number of sweeps. The vertical bars indicate a rate of 100 pulses per second, and the dots represent the bestfitting sine wave for the response. Note the increasingly sinusoidal character of the response produced by adding larger amounts of noise with little change in the bestfitting sine wave.

vector sum of the results of the three individual histograms. However, the mean square deviation of the data from the curve fitted to the sum of the histograms is only about 50 per cent higher than any of the individual histograms. Thus, spatial averaging over a number of nerve fibers should result in a very considerable increase in the signal-to-noise ratio when individual fibers are phase locked to some extent.

FIGURE 6 Poststimulus time histograms as in Figure 4 for neural analogues discharging at approximately (A) two, (B) three, and (C) four spikes per sinusoidal cycle and the sum (D) of these three histograms. The dots give the bestfitting sine curve to each histogram. The amplitude of the sine curve fitted to the sum of the histograms (D) 78.1 pulses per second is very close to the sum of the individual amplitudes (A) 35.9, (B) 22.8, and (C) 19.4 pulses per second. The phase of the sum is also very close to that of the

long enough so that end effects caused by starting or stopping the stimulus can be neglected.

Gerstein (this volume) has shown that the discharges of many central neurons are correlated. Moreover, the mean rate and other parameters of single nerve cells in a population often vary considerably, and the times of interest are often not long enough to make the third criterion above valid. Thus, the requirements for ergodicity are not fulfilled, although spatial averaging over a number of cells, as opposed to temporal averaging, has considerable advantages. Figure 6 illustrates the advantages of spatial summation by showing the response to a 20-Hz sine wave of neural analogues discharging with some variability at 40, 60, and 80 pulses per second. At all three frequencies, there is considerable phase locking. The sum of the three histograms is also shown (Figure 6D), and is relatively smoother than any of the three individual histograms. The best fit to the sum is very close to the sum of the best fits for individual

histograms, so averaging three units produces a signal three times as large. The root mean-square deviation from the fitted curve is only 1.5 times as great. Thus, a very considerable reduction in distortion results from spatial averaging over even three units, which would not be achieved by further temporal averaging of single units that show phase locking to the stimulus.

Summary

Four main conclusions result from the material presented here:

1. Nerve fibers can transmit very little information, particularly about rapidly varying stimuli, over any considerable distance with the use of a code based on analogue parameters of membrane potential.

2. The ability of nerve cells to transmit information about maintained stimuli by use of only the mean number of im-

pulses discharged in a period of time (frequency coding) can be calculated and compared with behavioral estimates. Neuronal variability severely limits this capacity.

3. With cyclic stimuli, the presence of neuronal variability prevents distortions caused by the phase locking of the response to the stimulus. Parameters such as the variance of intervals in a spike train may be adjusted for efficient information transmission, with little distortion over a given range of sensory stimuli, rather than themselves conveying information.

4. Use of a number of channels in parallel (spatial summation) further reduces distortion and can permit the details of a time-varying stimulus to be accurately transmitted.

The Topology of the Body Representation in the Somatic Afferent Pathway

GERHARD WERNER

IN THE COURSE OF the past 30 years, experimental studies and clinical observations firmly established the existence of a fixed relation between regions on the body and areas on both the sensory and the motor cortex. This suggested the idea of an orderly and systematic mapping of peripheral events in the brain (cf. Adrian, 1947). Specifically, neuroanatomical and neurophysiological studies determined that the spatial orderliness of the representation of the body at the cortical receiving areas and at subcortical relay stations follows the segmental (i.e., dermatomal) innervation pattern of the body periphery, at least in the medial lemniscal system and as far as overlap between consecutive dermatomes permitted one to recognize (Woolsey et al., 1942; Rose and Mountcastle, 1959). Equally abundant is the evidence that the cortical and subcortical projections in the visual system are also topographically organized, in the sense that fiber tracts and neurons preserve the general spatial arrangement that is to be found in the retina itself (Talbot and Marshall, 1941; Bishop et al., 1962; Garey and Powell, 1968; Whitteridge, 1965).

Prior to these discoveries, the notion of topographic orderliness of sensory projections was part of some of the psychophysiological theories of the nineteenth century, notably those of nativistic inclination. These theories, and in particular the theory of Bernstein (1868), postulated that perceived space is correlated with spatial relations established in the nervous system. At least in some degree, the neurophysiologists of the 1940s and 1950s seemed to supply the evidence needed to validate these older views, as well as Köhler's pronouncement of 1929 that "all experienced order in space is a true representation of a corresponding order in the underlying dynamical context of physiological processes."

Objections to applying the results of neurophysiological mapping studies as a basis for psychophysiological theories were, however, inevitable. In 1958, Doty produced evidence which led him to conclude that "the topographical arrangement of the retino-cortical projection is in itself of minor or no importance in the visual analysis of geometric patterns" (see also Doty, 1961). Nevertheless, the spatial orderliness of sensory mapping recurs with considerable persistence in diverse neural structures, the complete topographical representation of the cochlea in each of the 13 divisions of the human cochlear nucleus being, perhaps, the most illustrative example (Lorente de Nó, 1933). Therefore, reasons remain for inquiring into finer details of the mapping process that underlies the regularity of correspondence between an array of neural elements in the central nervous system and the peripheral sites they represent. Specifically, the question is whether some form of "coding" for the place of a sensation can be attributed to this mapping process, perhaps similar to that envisaged by Head (1920) to subserve, as a permanent physiological disposition, the appreciation of position and extension of a stimulus in a field of spatial relations (see also Oldfield and Zangwill, 1942).

For an investigation of the basic principles of mapping in the central nervous system, and of its possible implications, the component of the somatosensory system commonly designated as the dorsal column-medial lemniscal system offers features that promise to be particularly revealing. This system represents not only the cutaneous body surface, but, in addition, the receptors in joint capsules and periost situated in the space enclosed by the body surface. Thus, the question arises as to how this neural system accomplishes the task of mapping both the surface and the interior of the three-dimensional body periphery.

The tactile-kinesthetic system of primates

In the primate organism, the dorsal column-medial lemniscal component of the somatic sensory nervous system subserves the modalities of touch and kinesthesis with exquisite specificity and synaptic security (Rose and Mountcastle, 1959; Mountcastle, 1961). Its anatomical constituents are the afferent nerve fibers which originate from peripheral receptors, ascend in the posterior funiculi of the spinal cord, form synaptic relays in the dorsal-column nuclei and the ventrobasal nuclei of the thalamus, and finally project to a

GERHARD WERNER Department of Pharmacology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania

map-like representation of the body in the postcentral gyrus of the cerebral cortex, i.e., somatic sensory area I (S-I) (Woolsey et al., 1942).

In the projection of afferents from the body to the cortex, the neurons receiving sensory signals from tactile (cutaneous) and kinesthetic receptors are arranged in separate cell columns, oriented perpendicular to the cortical surface. For the neurons composing each "modality pure" cell column, Powell and Mountcastle (1959) ascertained that the peripheral receptive field (RF) of a neuron situated at one depth of a cortical cell column is representative for the approximate RF location of all neurons of that same cell column. Therefore, the neurons of each cell column contribute but one body area to the cortical body representation, and the cell columns are the elementary units of which the cortical map is composed. The cell columns of the two submodalities (i.e., the tactile and the "deep" modality) intermingle in a mosaic in which cell columns with RFs interior to the body surface and columns representing the overlying skin area are in proximity to one another. Although the cortex has extension in depth, the cortical map is equivalent to a two-dimensional sheet to which each cortical cell column as a whole contributes only one receptive field. This circumstance enables one now to state the problem of the preceding section in more specific terms: one can view the projection to somatic sensory area I as a solution of the geometric problem of mapping the surface as well as the interior of a three-dimensional body onto a single two-dimensional plane.

The map of the hind limb in the somatosensory area I

Because our primary interest was to determine with fine resolution what aspects of the body geometry are preserved in the body's cortical representation, we performed microelectrode penetrations that would cut across many neighboring cell columns of the cerebral cortex of the macaque. The penetrations were oriented in various directions with regard to the mediolateral and anteroposterior boundaries of somatosensory area I. Accordingly, we directed the microelectrodes in such a manner that they would traverse several millimeters of cortical tissue as nearly parallel to the cortical surface as possible, in view of its curvature and gyration. The data from these electrode traverses were supplemented by others obtained in penetrations perpendicular to the cortical surface, or with small deviations from the perpendicular (Werner and Whitsel, 1968).

Figure 1 illustrates, as an example, the data from one particular microelectrode penetration, which, in addition to the orientation from lateral to medial in the coronal plane, also subtended a small angle from anterior to posterior in the sagittal plane. The composition of the data, such as those illustrated in Figure 1 and obtained in 43 histologically verified penetrations, enabled the delineation of the hind-limb representation in S-I, which is displayed in Figure 2 (Werner and Whitsel, 1968).

The general plan of the map in the anteroposterior direction is that the receptive fields of the neurons progress, essentially, in bands around the limb, much as did the laces of a Roman soldier's footwear. Medially on the cortex, the postaxial leg representation changes continuously into a preaxial representation at the anterior and the posterior borders of somatosensory area I; the converse occurs laterally on the cortex where postaxial RFs at the anterior and posterior borders of the cortical map adjoin the preaxial leg representation. These "fringe" zones of the map tend in both cases toward the respective midlines of the limb (Figure 2).

Another characteristic feature of the composite map shown in Figure 2 is the representation of the dermatomes in their serial order, as indicated by the brackets to the right in the figure. The sacral dermatomes project medially to the cortex, and their preaxial fringes occupy the rostral and the caudal borders of their representation. The lumbar dermatomes project laterally on the cortex, and their postaxial fringes occupy the rostral and caudal borders of the map. There is a particular sequence of RFs within each dermatomal band in the cortical map as the microelectrode traverses that band from medial to lateral; in the cortical region of the sacral dermatomes the RFs progress from proximal to distal on the leg; conversely, in the cortical dermatomal bands of segments L-6 and L-5, the RFs progress from distal to proximal on the leg.

The position of the foot in the map between postaxial and preaxial dermatomal projection is in accord with its principal dermatomal affiliation to dermatome L-7. The RFs of the neurons of this latter dermatomal band move from lateral to medial on the foot as one traverses the cortical map from medial to lateral. As a result, the sum total of all RFs represented in any mediolateral traverse of the cortical map describes a continuous spiral path around the limb.

Such a way of looking at the relation between the body and its cortical image is the reverse of the experimental approach: instead of determining the projection from the body to the cortex, we propose to examine the relation between linear arrays of cortical neurons and the peripheral patterns made up from the sum total of the RFs of these same arrays of cells. The schematic displays of Figure 3 are predictions of this relation, based on the experimentally determined landmarks of the cortical map. The mediolateral cortical traverse in Figure 3 (left) corresponds to a hairpinlike peripheral path, crossing the sole of the foot from lateral to medial; another cortical traverse is seen to involve RFs from the sole and dorsum of the foot, in that sequence

FIGURE 1 A microelectrode penetration through somatosensory area I of the macaque. The electrode advanced from lateral to medial in the coronal plane and, to a lesser degree, from anterior to posterior in the sagittal plane. Diagram of the cortical surface is in the lower portion of the figure. Right-angled arrows indicate the plane of the coronal section containing the electrolytic lesion at the end point of the penetration. Descending arrow shows the electrode track as viewed from the cortical surface. Projection drawing of the coronal section containing the lesion shows the entire electrode track as well as the approximate depth of each isolated

and identified cortical neuron. Neurons responding to skin stimuli point to the left, and neurons driven from joints and periost to the right, of the track. Lines crossing cortex indicate the orientation of the cell columns. The modality and receptive-field center of each unit are displayed by codes on the appropriate region of a figurine (see key in lower right corner for an explanation of codes; MUR, multiunit record). Figurines are arranged in the sequence in which the neurons were encountered in the microelectrode penetration. (By permission of the American Physiological Society.)

(right, Figure 3). These and all other peripheral paths which correspond to mediolateral cortical traverses progress on the leg from proximal to distal, traverse the foot from lateral to medial, and ascend the limb from distal to proximal.

Furthermore, the cortical map of Figure 3 demonstrates that the geometrical properties of the cortical body representation appear quite different from those of the body itself, for several reasons. First, unlike the relation in the body periphery, the projection from the skin does not form a continuous boundary in the cortical map, enclosing the projection from the "deep sensors." A second reason for the difference between the body and its map is that relations of proximity and distance between points on the body do not consistently remain preserved in the cortical map; for instance, RFs on the heel of the foot and the dorsum of the ankle are closely adjacent or contiguous on the body, but they map to the far ends of the anterior and posterior edges, respectively, of the cortical projection of dermatome L-7.

Most of the penetrations were directed through the cortical area of the hind-limb and trunk representation, and the discussion focuses on the projection of this body area. However, additional data on the forelimb representation are in accord with the idea that the general principles of the conclusions apply also to the body projection as a whole.

FIGURE 2 Schematic map of the hind-limb representation in somatosensory area I. The labels medial, rostral, lateral, and caudal indicate orientation of this map on the cerebral cortex. Abbreviations on the medial and lateral boundaries of map refer to positions on the body: AM, anterior midline; DA, dorsoaxial line; PoM, posterior midline; VA. ventroaxial line. Arrows in the map point in the direction of the dermatomal trajectories. Within the area of the foot projection, the labels proximal, distal, medial, and lateral refer to positions on the foot. Brackets to the right of the figure label the dermatomal bands of the cortical map. The zig-zag shape of the axial lines indicates transition zones between preaxial and postaxial leg representation in the map. Shaded band that encloses the foot representation stands for neurons the RFs of which link dorsum and sole of foot, or the foot with preaxial or postaxial calf, respectively. Diagonal band separating sole and dorsum represents the neurons with RFs on the tip of the toes. (By permission of the American Physiological Society.)

The topology of somatic sensory area I

These apparent discrepancies between the geometrical properties of the body and its map preclude a simple correspondence between the two, at least in the framework of ordinary spatial intuition which is based on the metric structure of space, i.e., on relations of proximities and distances of points. For the purpose of characterizing how one space maps to another, however, it is possible to conceive of spaces that possess a different and more general structure than is inherent in a metric structure. The requirement is that such spaces can be described by a list of sets of elements, and that the unions and intersections of these sets must themselves be members of the list. Then it is said that the list of sets, their union and intersections, and the null set form a topology. The mapping between the two spaces is said to be a homeomorphism if every set of the topology in one space corresponds uniquely to a set in the other space, and vice versa. Figure 4 illustrates these definitions for the two simple topologies T and T*. If the mapping between the two spaces can be shown to be a homeomorphism, it follows that any topological property of one space is also a topological property of the other (see, for example, Hu, 1966; Lipschutz, 1965).

FIGURE 3 Schematic display of two medial-lateral traverses through the hind-limb position of somatosensory area I. Figures at the bottom display the paths on the body, consisting of the totality of RFs that one would encounter in microelectrode penetrations that cross the cortical projection in the manner indicated in the diagrams at the top. The dotted portion of the path traverses the dorsum of the foot, which cannot be seen in this view. (By permission of the American Physiological Society.)

To apply these concepts to the characterization of the somatosensory projection, it is necessary to determine properties of the body and the cortical map which can be identified with topologies, in the sense of the preceding definition. The paragraphs that follow describe the interpretation of certain patterns of RFs on the body and of neurons in the cortex as topologies, and prove that the mapping between the body and its cortical image is a homeomorphism.

The clue of this analysis is the observation that the afferent fibers at the entry zone of each dorsal root and in the corresponding fiber laminae of the posterior funiculi in the

FIGURE 4 The upper portion illustrates two topological spaces, T and T*. In T, the array of elements {a,b,c,d} forms the sets as shown. T is a topology because all unions and intersections of the sets {a,b}; {b}; {c,d}; and {b,c,d} are themselves members of the list of sets; e.g., {c,d} \cap {b,c,d} = {c,d}, which is a member of the list. Similarly, the sets {x,z}; {y,w}; {z}; and {y,z,w} have been chosen from the array = {x,y,x,w} to form a topology. The lower portion illustrates the idea of a homeomorphism, h, for it shows a mapping h which uniquely relates sets in T to sets in T*, and vice versa. An example for h is: {a,b} \leftrightarrow {x,z}; {b} \leftrightarrow {z}; {c,d} \leftrightarrow {y,w}; {b,c,d} \leftrightarrow {y,z,w}.

spinal cord are arranged in a certain order (Figure 5) (Werner and Whitsel, 1967). In each dermatome, a family of linear arrays of afferent fibers can be discerned; the orientation of these linear arrays in the dorsal roots and in the corresponding portions of the posterior funiculi is shown in Figure 6B. The distinguishing property of the fiber arrays with their orientation, indicated by the arrows, is that they represent peripheral RFs which, if taken together, combine in each segment to an essentially continuous path in the periphery (Figure 6A). We designated each path that can be generated in this fashion as a dermatomal trajectory (see Figure 5). Within each dermatome, all trajectories have a common direction on the body. The trajectories of consecutive dermatomes, although partially overlapping, form a loop around the hind limb, as shown schematically in Figure 6A. The afferent fibers from deep and cutaneous receptors in a dermatomal trajectory intermingle, the sole criterion of fiber order being the sequence of the RFs along the trajectory.

To emphasize the characteristic features of the body representation in the posterior funiculi of the spinal cord, it can be examined from the point of view of a hypothetical observer capable of "reading" the RF labels carried by individual afferent fibers. As this observer moves along from dorsomedial to ventrolateral in the spinal cord crosssectional plane (Figure 6B), he would traverse a path on the body which begins postaxially at the sacrum and hip, descends to the lateral edge of the foot, crosses the foot from lateral to medial, and ascends the leg preaxially toward groin and hip (Figure 6A). On this path, the observer would "see" receptive fields on the surface of the leg intermingled with others deep in the leg, but at no point would he cross a continuous boundary which would enable him to tell whether he is at the "inside" of or "on" the body surface.

In the projection to the cortex, the dermatomal trajectories retain a characteristic role. This is illustrated in Figure 6C. In the cortical region of the sacral dermatomes, the RFs progress from proximal to distal on the leg. Conversely, in the cortical dermatomal bands of segments L-6 and L-5, the RFs progress from distal to proximal on the leg. The projections of the foot fall between segments S-1 and L-6; the RFs of the neurons in this cortical band progress sequentially from lateral to medial on the foot as one traverses its cortical map. As a result, the sum total of all RFs represented in any mediolateral traverse of the cortical map describes a continuous loop around the limb (see also Figure 3).

There is one striking difference between the appearance of this cortical path and the path traversed by the hypothetical observer in the posterior funiculi: the path would not be smooth; rather, the observer would see sequences of RFs which progress continuously along the body, but at each transition to the next dermatome he would backtrack part of the sequence just completed. Thus, his course would vacillate as he proceeded to complete the loop. In contrast, the cortical observer would find that to each cortical traverse in the direction shown in Figure 6C, there corresponds a continuous progression of RFs around the limb, as a result of dermatomal overlap in the cortical projection. It appears that the afferents from the dermatomal trajectories in each loop around the limb assemble according to the body region of origin.

In the projection from the periphery to the cortex, the body is first segmented into a series of overlapping dermatomes whereby the afferents from each dermatome retain a specific order; namely, that of the dermatomal trajectories. The trajectories align and partially superimpose to the effect that they map a continuous path on the body. Therefore, it appears that the body and the cortical map can be considered a composite of dermatomal trajectories, and that

FIGURE 5 Schematic representation of the peripheral body regions innervated by fibers entering dorsal root L-6, and the position these fibers occupy in the root and the fasciculus gracilis. Regions within the dermatome (1-4) and the location of their afferent fibers in the dorsal root and fasciculus gracilis are indicated by corresponding codes. (By permission of the American Physiological Society.)

FIGURE 6 The role of the dermatomal trajectories in the somatosensory projection. A. A view of the hind limb with a hairpin-like path on its surface that is shown to consist of afferents in three dermatomes. The full line is the trajectory in S-I; it overlaps at its distal end with a trajectory in L-7; on the preaxial side, the loop is completed by a trajectory in L-6. The symbols of the respective trajectories are the same in A through C. Where the lines of the trajectories run in parallel, there is overlap between adjacent dermatomes. B. The position and direction of the dermatomal trajectories with the peripheral paths shown in A, as they appear in the

dorsal roots and the fiber laminae of the posterior funiculi of the spinal cord. In the latter, the arrows of the trajectories point from dorsomedial to ventrolateral, as the cord is positioned in the body. C. The projection of the hind limb to somatic sensory area I, with the dermatomal trajectories that run side-by-side in the cortical map, as they do in the body periphery (see A). The landmarks of the map in C are as follows: AM, anterior midline; DA, dorsoaxial line; PoM, posterior midlimb; VA, ventroaxial line. Note that the hairpin-like path in the periphery appears on the cortex as a straight and continuous traverse of the map.

each dermatomal trajectory is treated in the projection as a unit, and it maps as a whole. This type of projection enables one, in the language of topology, to interpret the body as an aggregate of RFs that combine to ordered sets in the form of the dermatomal trajectories. Similarly, the cortical map appears in the projection as an aggregate of neurons that also combine to ordered sets, each set receiving afferents from one dermatomal trajectory. The totality of all ordered sets in the periphery is a topology in the body space, as are the sets of neurons in the cortical map. In the mapping, each set of elements in the periphery comes to correspond to one set of elements in the cortex, and vice versa; consequently, the mapping is a homeomorphism. Accordingly, the body and its cortical map are topologically equivalent in this sense: two adjacent peripheral RFs that form part of one trajectory remain neighbors in the cortical projection. Neighboring RFs that belong to different trajectories need not, however, always be neighbors in the cortical map; they are not if their afferents enter the spinal cord at different segmental levels.

The spatial characteristics of the cortical map

We are now in a position to develop a rigorous argument that the body representation in the cortical map has the property of a nonorientable surface. The argument rests on the principle that a surface can be specified by the orientation of its edges and their sequence, as one moves around the perimeter of that surface in a predetermined direction. An edge is marked with the exponent (-1) if its orientation is opposite to the direction around the perimeter. The entire sequence is set equal to 1 as a notational device to show that the complete perimeter of the polygon has been given (see, for example, Blackett, 1967; Alexandroff, 1961).

This procedure is applied to the schematic hind limb of Figure 7 which defines the cortical map unambiguously as the surface of a Klein bottle (see legend to Figure 7).

This topological characterization of the cortical map implies also a set of rules for approximating a model of the cortical map in three-dimensional space. The individual steps of this construction are depicted in Figure 8. To construct a three-dimensional model of the Klein bottle, one would first roll the plane of the cortical map into a cylinder so that the interior edges of Am-PoM of the left map in Figure 7 come to superimpose; next, one would bend the cylinder, rotate the bottom plane by 180 degrees, and bring the bottom opening into superposition with the top opening. The last step would require that the surface of the cylinder intersect itself. The individual steps of this construction are depicted in Figure 8. The important characteristic of the Klein bottle and, therefore, of the cortical map as well is that it is nonorientable. The model of Figure 8 makes this intuitively clear, for there is no distinction possible between inside and outside, as one imagines a point to move along the surface of this model; nowhere would this point encounter a boundary.

The process of self-intersection which was part of the set of procedures used to aid in the visualization of the Klein bottle is physically not realizable in three-dimensional space; therefore, the model of Figure 8 is merely a stylized approximation. The principle we employed in this procedure is the ability to describe a space Y (i.e., the Klein bottle) as obtained by identification from a simpler space X (i.e., the cortical map). The description may be adequate to show the properties of Y, even though Y cannot be properly visualized.

FIGURE 7 A schematic picture of the hind-limb portion of the cortical map. The anatomical body landmarks are indicated to permit identification of edge orientation and correspondence of edges. The abbreviations for these landmarks are the same as those in Figure 6D. The two lateral edges, AM-PoM, represent identical zones on the body periphery: they are interior edges of the map, and their orientation is that of the RF progression of the dermatomal trajectories, indicated by the anows labeled b. To establish the orientation of the upper and the lower edges in the map, we transform the polygon of the cortical map, as shown by the

shaded areas in the figure. The figures to the right and to the left are topologically equivalent. We merely remove the shaded triangle of the left side of the polygon and join it to the right side of the polygon, making sure that the proper landmarks superimpose. This transformation proves that the upper and the lower edges of the original polygon have an opposite orientation. We can now assemble the complete edge equation: a.b.a.b.⁻¹ = 1. This equation defines the cortical map unambiguously as the surface of a Klein bottle.

FIGURE 8 The sequence of operations to fold the cortical map in somatosensory area I to a three-dimensional model of a Klein bottle. (This figure was designed by T. Melnechuk of NRP.)

Implications for the haptic sense

Animals and man possess the mode of behavior and experience known as haptics (Gibson, 1966; Révéz, 1950). The latter goes beyond the functional capabilities of the individual modalities of touch and kinesthesis in isolation; rather, in certain invariant combinations, the two sense modalities are thought to specify jointly the stimulus information of the form of objects in an environmental space. One might argue that this presumes a functional unit between sensory events signaling the position of external objects with respect to the body, and sensory events signaling the position of body parts relative to one another such that "skin space and bone space are all one piece" (Gibson, 1966). The suggestion is that the tacile-kinesthetic representation in one common map is the mechanism by which the central nervous system combines contactual information about objects in space external to the body, and of geometric information from within the body into one common space, suited to reflect the haptic sense.

The general implications of this conceptualization are that the sensory representation in the cerebral cortex can possess properties that are not inherent in the raw data originating from the peripheral sense organs themselves, and that the nature of new properties can be a consequence of the characteristics of the neural mapping process which links body periphery and central sensory representation.

Somatosensory spaces and abstract mapping

The definition of a topology on the body periphery and in the cortical map was based on the concept of the dermatomal trajectory. With respect to those peripheral stimulus configurations that are part of the dermatomal trajectory, the relation of a homeomorphism between body periphery and the cortical image was ascertained in the preceding sections of this report. We shall now discuss the mapping of any arbitrary path, not necessarily coinciding with a dermatomal trajectory. The most striking characteristic of the experimentally determined geometric relation between the periphery and its cortical map in somatosensory area I is that any linear array of neurons in S-I (such as is traversed by a surface-parallel microelectrode penetration) traces on the body a continuous path of RFs (see, for example, Figure 1). But the converse is not generally true: to illustrate this, we select the peripheral path $1 \rightarrow 10$ on the body as shown in Figure 9. This path is composed of several dermatomal trajectories. Accordingly, the cortical image that can be predicted from the experimentally determined landmarks and other properties of the cortical map will not have the simple appearance of the mapping of a single dermatomal trajectory as illustrated in Figure 3. Rather, as shown in Figure 9, it will consist of fragments of the cortical images of those dermatomal trajectories that compose the peripheral path $1 \rightarrow 10$: for instance, the portion $1 \rightarrow 5$, which on the body is a composite of a dermatomal trajectory in L-6 and S-1, will map the cortical images $1'' \rightarrow 5''$ and $1' \rightarrow 5'$, respectively. Similarly, the portion $6 \rightarrow 7$ on the body will appear in a cortical region of dermatome L-7 in the form of a U, reflecting the reversal of direction as the peripheral path progresses from its preaxial to its postaxial position.

If one now applies the instructions of the previous section to embed the planar cortical map according to its topological characteristics in three-dimensional space, it becomes apparent that the branches of the cortical image $1' \rightarrow 10'$ and $1'' \rightarrow 10''$ in the planar map can combine on the surface of the Klein bottle in three-dimensional space to *one* continuous image of the peripheral path $1 \rightarrow 10$.

One way to conceptualize some possible implications of these relations between the body and its map in S-I is to employ the idea of the *path-lifting property* of mappings as an interpretative device (Hurewicz, 1955; Fadell, 1959; Hu, 1959). The heuristic power of this line of thought was demonstrated by Greene (1964) in an attempt to formalize the relation between spaces of various degrees of abstractness.

The essentials of this line of thought are schematically illustrated in Figure 10. Let B represent the metric space of the body in which P' designates an arbitrary stimulus pattern (e.g., a path, with a beginning in O'); let C stand for the cortical map in S-I, which, as experiments established, projects by p continuously onto B (see above).

Furthermore, let Y represent a structure in the central nervous system that contains a repertoire of stimulus specifications, $O'_iP'_i$, of which E_i is a specific instance. To

FIGURE 9 Diagrammatic representation of an arbitrary peripheral stimulus configuration (shown as path $1 \rightarrow 10$ on the limb) in the schematic cortical map of somatosensory area I in the postcentral gyrus.

give an example: an element in this repertoire could be the concatenation of a path, P', with a starting point, O'; this example is chosen because of its obvious analogy to the type of concatenations known to occur in the visual system as the characteristic of hypercomplex cells (Hubel and Wiesel, 1962, 1968).

If there exists in this system a mapping, f: $Y \rightarrow C$, and an inverse mapping, l, such that the sequence of mappings, $l \times f$, projects E_i back onto itself, then p: $C \rightarrow B$ has the *path-lifting property* and f is said to be a *lifting function*; moreover, if f exists, it follows that a mapping, l_p , can be found that determines the image of O'P' in C.

In more general terms, given these prerequisites, if the repertoire of central representation in Y contains signal specifications that correspond to a particular peripheral stimulus event, O'P', then a procedure exists for finding a mapping of this event in C. In that sense, C may be viewed as possessing a "model" of B with respect to the specifications contained in Y. Similarly, C can depict classes of states of B that are "well formed" and admissible with respect to rules laid down in Y.

The formal resemblance to Sutherland's (1968, 1969) theory of visual pattern recognition is apparent: the mappings f and l reflect the interactions between a "processor," C, and a "store," Y. The latter fulfills the role of a device that evaluates projection patterns from the periphery to C, in terms of their conformity with "schemata" stored in Y. That part of the total projection pattern in C that is relevant for the "recognition" by Y can be considered a mapping of

O'P' to C under the mapping function l_p . Accordingly, the matching process between OP and E_i is equivalent to the computation of a mapping function, l_p , such that l_p : O'P' \rightarrow OP. The advantage of expressing these relations in the framework of lifting functions is that the latter implies the existence of a solution, l_p , relative to Y in all instances, provided the existence of the functions l, f, and p, and with B being a metric space.

FIGURE 10 A visual representation of the concepts of "path-lifting property" and "lifting function."

The existence of p is experimentally established: it is that continuous mapping function that depicts any linear array of neurons on the cortex as a continuous path of RFs on the body (see above). The mappings l and f can be equated with neural connections between specific cortical receiving areas and "intrinsic" cortex lacking specific thalamocortical projections (Rose and Woolsey, 1949). Neurological and neurobehavioral studies suggested that the intrinsic cortical sector operates by efferents on the events occurring in the extrinsic cortical mechanisms and, thereby, accomplishes the partition of events occurring in the extrinsic system into elements of increasing complexity (Pribram, 1959). In this concept, the intrinsic sectors are conceived as programing mechanisms that function to partition events initiated by the sensory input into complex categories.

The general manner in which cortical receiving areas (exemplified by C in Figure 10) and a repertoire of interpretative rules, Y, are proposed to interact in the model with path-lifting property formally mimics the process of parsing a sentence and is, therefore, in line with the idea that linguistic analysis provides a model for description of *all* kinds of behavior (Miller et al., 1960).

Is there a common principle in somatosensory mapping?

The experimental results reviewed in the preceding sections ascribed a specific connotation to the general idea of "topographic orderliness" of cortical representation (see beginning of this paper). In the first place, this orderliness reflects in S-I the fact that the net shift of RFs along linear arrays of cortical cell columns traces a continuous path on the body. Second, it is as if, for the purpose of mapping, the body periphery were decomposed into more-or-less narrow bands, and as if the afferents from these same bands assembled again in the cortical receiving areas to terminate on corresponding linear arrays of cell columns. It is now established that the projection to the second somatic area (Woolsey, 1943; Woolsey and Fairman, 1946) follows the same rule of mapping, except for the deletion of the "deep" submodality and for the introduction of the bilateral symmetry of the cutaneous representation (Whitsel et al., 1969).

In the projection to the first and second somatic areas, the fragmentation of the body into bands follows a specific order: the first-order afferent fibers with receptive fields on the body enter the spinal cord along its rostrocaudal extension in a characteristic sequence, namely, that of the "dermatomal trajectories" (Werner and Whitsel, 1967, 1968). The mapping of the body to the cortex represents the family of the trajectories rather than the body topography as such.

To view the cortical mapping in somatosensory areas I

and II in this manner has, perhaps, some bearing on the understanding of the developmental factors that lead to these maps, for it permits one to see a rank order in the first-order afferent fibers, given by the sequence of entry along the rostrocaudal spinal axis. In the mapping, these afferents sort themselves to restore this peripheral rank order "like soldiers, on the next man" (Horridge, 1968). The important point is that, whatever carries in each nerve the label of rank order, it is preserved in the projection to the cortex, even if the afferents travel different central pathways, for in S-II the afferents arrange in the same rank order as they do in S-I, although the projection to the former is composed of distinctly different ascending pathways, which merge into one cortical representation pattern (cf. Bowsher, 1965).

This view establishes a connection to some current ideas which conceptualize morphogenesis in terms of computer programs and automata theory (Ulam, 1962; Arbib, 1967; Stahl, 1966; Apter and Wolpert, 1965; Bonner, 1965). The implication is that it is more meaningful to discuss a complex pattern (such as a cortical map) in terms of a set of instructions that can generate it, than in terms of the information contained in the final product. Accordingly, in a program that would generate the geometry of central projections, the sequence of entry of first-order afferent nerve fibers into the neuraxis would be a distinguishing attribute, capable of imparting an essentially identical topology to all central representations of these afferents. One is then led to conjecture that the multiplicity of central representations of a given set of peripheral receptors, each topologically in register with all others and each abstracting a different stimulus feature (cf. Maturana et al., 1960; Hubel and Wiesel, 1962, 1968; Werner and Whitsel, 1970), enables the parallel processing of sensory input similar to that applied in the design of pattern-recognition machines (Selfridge and Neisser, 1960).

55 Signal Transmission Between Successive Neurons in the Dorsal Spinocerebellar Pathway

JAN K. S. JANSEN and LARS WALLØE

FORMULATION of an adequate model for studying the efficiency of signal transmission in central neurons requires, initially, a quantitative determination of the entire neuronal input and output. The neuronal output is ordinarily simple to record as somatic or axonal spikes. Usually the input is much more difficult to determine. The present paper is, therefore, a discussion of the neuronal properties that are most important for the input-output transformation and of the extent to which the input activity of a neuron can be inferred from its output behavior.

The study of sensory pathways offers obvious advantages for such a purpose. The most important of these is the possibility of input control by adequate stimuli to the relevant receptors. However, in many sensory systems, there are complex neuronal interconnections at even early stages of signal transfer, and these represent a major obstacle for the interpretation of the transfer under physiological conditions. The complexity is presumably due to the complex content of the relevant signals. For instance, in general somatic, auditory, and visual pathways, space parameters, as well as intensity parameters, of the stimulus are of obvious physiological significance. Therefore, in our attempt to study the transfer of signals in a nerve cell we have selected the second-order neurons of the dorsal spinocerebellar tract (DSCT) which offer several advantages. 1. The synaptic coupling of the system is comparatively well known (Lundberg, 1964; Oscarsson, 1965). 2. The properties of the relevant receptors (muscle spindles and tendon organs) have been studied extensively, and they give slowly adapting signals to steady-state inputs (Matthews, 1964; Jansen and Rudjord, 1964; Houk and Simon, 1967; Alnaes, 1967). 3. The content of the firstorder signals can be described as functions of muscle length or tension. 4. The second-order neurons are localized in Clarke's column of the spinal cord; their perikarya, as well as their axons in the dorsolateral funicle of the cord, can be investigated with existing microelectrode techniques.

The present paper reviews some of our own work on the DSCT in cats and discusses its relevance to other groups of nerve cells.

The specificity of synaptic coupling

A high degree of specificity characterizes several aspects of the synaptic coupling of the DSCT. Each group of secondorder neurons is activated by the stretch receptors of a given muscle and is usually not excited by the stretch of other muscles, not even close synergists. A second type of

JAN K. S. JANSEN and LARS WALLØE Institute of Physiology, University of Oslo, Norway

specificity concerns the connections from the different types of stretch receptors. Each second-order neuron appears to be exclusively, or at least predominantly, activated from primary endings, Golgi tendon organs, or secondary endings of a given muscle. This has provided the basis for the identification of the different types of secondorder neurons of the pathway (Jansen and Rudjord, 1965).

A final type of specificity is in the inhibitory connections within the DSCT. Although far from fully explored as yet, the pattern appears to be as specific as that of the excitatory connections (Jansen et al., 1967b). Thus, the tendon-organ afferents from the triceps muscle would inhibit the excitatory signal from pretibial flexor muscles, whereas the afferents from spindle primary endings inhibited the signal from the muscle of the great toe. These specificities of the synaptic couplings have enabled us to generate homogeneous excitatory or inhibitory inputs to the second-order neurons and thereby facilitate the interpretation of the neuronal behavior.

The linear input–output relationship

The second-order DSCT neurons give a maintained discharge to a maintained excitatory input. Two types of input have been studied systematically. The simplest is an excitation of the cell with a depolarizing transmembrane current step (Figure 1A). After an initial overshoot, the firing rate settled at a new steady level, at which it remained apparently indefinitely. The rate of firing increased linearly with increasing current intensity over a surprisingly wide range, at least up to 200 impulses per second (Figure 1C). The slope of the frequency current curves varied between 5 and 9 imp/sec/nA, with a mean of 6.7 (Eide et al., 1969a). The DSCT neurons appear to be unique among neurons so far studied in their wide range of linearity.

A comparable type of response is found in a maintained synaptic excitation elicited by muscle stretch (Figure 1B). Again the cell firing continued as long as the stimulus was maintained, and there was no indication of adaptation or fatigue in the synaptic transmission. As illustrated in Figure 1D, the firing frequency increased linearly with the degree of muscle extension. As it has been established that the rate of primary endings in muscle spindle increases linearly with muscle extension (Matthews, 1964), we may conclude that this synaptic transfer is linear as well. It is equally significant that the frequency range and the slope of the frequencyextension curve of the second-order neurons (3–5 imp/ sec/mm) are very much the same as those of the corresponding receptors (Jansen et al., 1966).

The importance of the linear input-output relations (Figure 1) is emphasized by additional observations on summation of synaptic and injected transmembrane currents. According to its direction, a constant transmembrane current adds or subtracts a given number of imp/sec independently of the level of synaptic activitation of the neuron. Similarly, a given synaptic input caused a constant increase in rate at all physiological firing levels, as a result of injected transmembrane current (Eide et al., 1969a). This shows that the synaptic currents and the injected currents act on a common spike-generating site in these DSCT neurons, as is also common in other nerve cells (Granit et al., 1963; Brown and Stein, 1966). It also permits an estimate of the average synaptic current generated by a 1-mm muscle stretch. With an average frequency-current slope of 7 imp/sec/nA (Eide et al., 1969a) and a frequency-length slope of 3.5 imp/sec/mm (Jansen et al., 1966), the average synaptic current is 0.5 nA per millimeter of muscle extension. We shall return to this when discussing the synaptic effect of each presynaptic impulse.

The input-output relation also has been investigated with sinusoidal stretch at different frequencies (Jansen et al., 1967c). Over the range studied and within the linear range of the stretch receptors, the frequency responses of the first- and second-order elements were indistinguishable. Accordingly, the transfer function of the synaptic transmission is frequency-independent over the range examined.

From comparisons between receptor response and psychophysical estimates of stimulus-response relations in the general somatic system, Mountcastle (1967) has suggested that the signal transformations that take place in these pathways are entirely linear. The nonlinearities that may be present in the over-all response appear to be due to the properties of the receptors. This important generalization and astonishing simplicity are supported at the first-order to second-order level by our observations on the DSCT.

This high degree of linearity is at present unexplained in terms of neuronal membrane properties. Stein (1967a) has shown that the Hodgkin-Huxley membrane equations generate a neuronal output that is essentially nonlinear. The rate of increase of firing frequency decreases rapidly with increasing excitation. Such behavior is seen, for instance, in the slowly adapting receptor of the crayfish (Enger et al., 1969). Motor neurons, on the other hand, exhibit a different type of nonlinearity (Kernell, 1965), in which the slope of the frequency current relationship is increased at higher levels of excitation. Kernell (1968) has given evidence that this may be caused by the prolonged afterhyperpolarization and the associated increase in membrane conductance. In DSCT neurons, the afterhyperpolarization is smaller than in motor neurons and apparently is caused by a different mechanism, because there is little concomitant increase in membrane conductance (Eide et al., 1969a). Also, when it is considered that their dendrites have largely unknown but probably nonlinear properties, it appears reasonable to suggest that the wide range of linearity exhibited by the DSCT neurons is the

FIGURE 1 Excitation of DSCT cells. A. Activation of neuron by outward transmembrane current step of 10 nA starting at the break of the base line and lasting throughout the record. Linear stretch of triceps muscle up to full physiological extension at a rate of 19 mm/sec in period indicated by line. Full extension maintained throughout rest of record. Extracellular axonal spikes recorded from

result of mutual canceling of several nonlinear relationships.

An additional feature of the output of DSCT neurons requires comment. DSCT cells commonly exhibit a highly regular background activity at a rate of about 10 imp/sec even without any specific primary afferent input (Holmqvist et al., 1956; Jansen et al., 1966). The mode of generation of the background discharge is at present unknown. Holmqvist et al., (1956) gave some evidence that it might be due to a low-level synaptic input from spinal interneurons, but, as discussed below, our simulation experiments make this appear doubtful.

The firing pattern

There is a striking difference between the regular firing pattern of DSCT cells activated by injected current and the

dorsolateral funicle. (From Jansen et al., 1966.) C. Steadystate firing frequency (ordinate) against intensity of outward transmembrane current (abscissa). Same cell as in A. Observations from experiments reported by Eide et al., 1969a. D. Steady-state firing frequencies (ordinate) against muscle extension (abscissa) for five different second-order neurons, each indicated by separate symbol. All observations from de-efferented preparations.

irregular firing pattern observed during activation by muscle stretch (Figure 1A, B). Such irregularity of firing is common in central neurons during steady-state activation (Hilali and Whitfield, 1953; Gerstein and Kiang, 1960; Werner and Mountcastle, 1963; Goldberg and Greenwood, 1966). Two hypotheses have been advanced to explain this irregularity of firing. One postulates a noise generator intrinsic to the neuron, such as a random fluctuation in threshold or membrane potential (Geisler and Goldberg, 1966). The second ascribes the irregularity of firing to the discontinous nature of synaptic transmission (Stein, 1965). For the DSCT neurons there is direct evidence in favor of the latter hypothesis. The background firing can be highly regular, and the characteristic irregularity appears immediately when activated synaptically. Accordingly, it appears reasonable that the fine structure of the firing pattern contains information about the synaptic input. A systematic description of the firing pattern is required to determine it. The initial part of this description is the probability of occurrence of intervals of different duration as estimated by the interval histogram. These are usually unimodal and fairly symmetrical (Figure 2A). Their shape, independent of the degree of activation of the cell, is different from that of many other neurons in the absence of an approximately exponential right tail. The degree of irregularity, as measured by the coefficient of variation (CV = SD/mean interval), is independent of the frequency of firing of the cell. This appears from the plot of the standard deviation of the distribution against its mean interval (Figure 2C). The observations are adequately described by a straight line, the slope constant of which gives the CV. The CV varies between approximately 0.3 to 0.6 for DSCT cells activated from the primary ending of muscle spindles. The background firing, on the other hand, may have a CV as low as 0.05 (Jansen et al., 1966).

Another important feature of the firing pattern of the DSCT neurons is the remarkable degree of serial dependency. The value of the serial correlation coefficient (R) is commonly as high as -0.6 to -0.8 for neighboring intervals. This means that there is a tendency for short and long intervals to appear alternatively. We shall return to the possible significance of the serial dependency. The value of R is independent of the level of excitation once the cell is firing above some 20 imp/sec (Jansen et al., 1966).

Synaptic mechanisms

Intracellular records provided direct information about the synaptic organization of the DSCT neurons. The first experiments showed that the synaptic transmission to the DSCT cells was qualitatively similar to that of motor neurons (Curtis et al., 1958; Eccles et al., 1961). The high efficiency of transmission, as evidenced by the large amplitude of the compound excitatory postsynaptic potential

FIGURE 2 Distributions of firing intervals of second-order neuron activated by 5 mm (A) and 14 mm (B) maintained the extension of the anterior tibial muscle. C. Relationship

between standard deviation and mean interval of firing at various degrees of maintained synaptic activation. All data from same cell.

(EPSP) to peripheral nerve stimulation, was also a feature of the early observations. In the following, we concentrate on two points of crucial importance for the interpretation of the firing pattern of the cells. These are the synaptic effect of each presynaptic impulse and the number of primary afferent fibers converging onto each second-order neuron.

With a small to moderate load on the appropriate muscle, characteristic short-lasting depolarizations appear in the membrane potential of DSCT neurons (Figure 3). Their rate of appearance increases with increasing load on the muscle, and from their time course they can be safely interpreted as EPSPs evoked by single presynaptic impulses (unitary [u] EPSPs) (Eide et al., 1969b). In favorable situations the u EPSP of a particular presynaptic fiber can be identified and followed by its amplitude and regularity of appearance. The regularity is due to their origin in musclestretch receptors, which fire regularly during steady-state activation.

There is a considerable variation in the amplitudes of the u EPSPs evoked from the different primary afferent fibers converging onto the DSCT neurons. The remarkable observation is, however, their large size. The largest u EPSP measured as much as 5 mV, and the average size of all the u EPSPs of Ia afferents to one neuron was 2.7 mV (Eide et al., 1969b). A second important finding was the relative constancy of the time course of the different u EPSPs. Because the period of transmitter liberation appears to be short in these cells (Kuno and Miyahara, 1968), the time course of potential change is determined by the position of the synapses in relation to the recording site, presumably in the cell body. Their constant time course, therefore, suggests that they are due to activity at synaptic terminations which are electronically equidistant from the cell body. The rapid time course and the large amplitudes of the EPSPs are

in agreement with the anatomical observation that primary afferent fibers end as "giant synapses" on the proximal dendrites of DSCT neurons (Szentágothai and Albert, 1955; Rèthelyi, 1968).

At higher levels of stretch, additional units are recruited, at which point the picture of the synaptic activity becomes complicated and the individual units cannot be identified separately (Figure 3). Therefore, the degree of convergence cannot be established in this way. Instead, it was determined from the ratio between the amplitude of the compound EPSP elicited by synchronous activation of all Ia afferents in the muscle nerve and the average size of the u EPSPs in the same neuron. Taking the nonlinear summation of EPSPs into account, we found, in a limited number of cells, 12 to 16 primary afferent fibers converging onto each secondorder neuron (Eide et al., 1969b), which suggests that something like 30 per cent of the primary endings of the muscle employed project to each neuron of this type. Although the range of variation is not established, additional data to be discussed suggest that the estimate is reasonable, and we can get a crude check on the observations. The average synaptic current per millimeter of stretch was 0.5 nA (see above). The average increase in firing frequency for each primary ending of the muscle employed is 3.6 imp/sec (Jansen and Matthews, 1962). The total input to a second-order neuron is therefore about 50 imp/sec/mm, and the average amount of charge removed by each presynaptic impulse becomes $0.5 \times 10^{-9}/50 = 10^{-11}$ coulomb. With a membrane capacity of 3×10^{-9} farad (Eide et al., 1969a), the average amplitude of the u EPSPs should be approximately 3 mV.

The large u EPSPs of DSCT neurons invite some comments on the mode of termination of the primary afferent fibers. The collaterals of the same Ia afferents terminate on motor neurons as well as on DSCT neurons, which il-

FIGURE 3 Unitary EPSPs of second-order neuron. Intracellular records. Increasing degrees of synaptic activity produced by loads of 10, 20, and 50 gram weight on the

tendon of the soleus muscle. (From experiments by Eide et al., 1969b.)

lustrates instructively the differences in synaptic efficiency and coupling on two groups of second-order neurons of entirely different function. The Ia afferents from a particular muscle appear to establish monosynaptic connections with all the homonymous motor neurons (Mendell and Henneman, 1968). The amplitude of their u EPSP is small (about 0.1 mV), because each presynaptic impulse liberates only 2 to 3 quanta of transmitter on the average (Kuno and Miyahara, 1969a). The monosynaptic excitation of heteronymous motor neurons is less efficient on account of a smaller degree of convergence on these. The mean quantal content of the heteronymous u EPSPs is, however, the same as that of the homonymous ones (Kuno and Miyahara, 1969b). On the DSCT neurons, on the other hand, approximately 30 per cent of the Ia afferents appear to converge onto each neuron, and the average quantal content of their u EPSPs appears to be at least 10 times that of the motor neuronal u EPSPs (Eide et al., 1969b). These differences have their morphological correlates in the extent of synaptic contacts at the two types of cells (Szentágothai and Albert, 1955; Haggar and Barr, 1950). The DSCT synapses appear to be constructed for signal transmission, and the motor-neuronal synapses, for signal integration.

From the point of view of the output of the second-order neuron, the amplitude of the u EPSP in relation to the firing threshold of the cell, rather than the absolute amplitude of the u EPSP (Stein, 1965), is the important parameter. The firing threshold of the DSCT cells proved difficult to determine, partly because of the background firing of the cells and partly because the cells are easily injured by microelectrode penetration (Eide et al., 1969b). Even so, observations were obtained suggesting that the simultaneous occurrence of as few as two to three u EPSPs might be sufficient to fire the second-order neuron.

A model of the second-order neuron

The problem discussed in this section is whether the observed firing pattern of the DSCT neurons can be explained quantitatively from the observed properties of the cells and their input. Various simplified models of nerve cells have been formulated, and their behavior has been explored by simulation on a digital computer (Walløe, 1968; Walløe et al., 1969). With the evidence at hand indicating that the irregularity of firing appeared to be associated with synaptic activation of the cells, the models have all been elaborations of the "quantal excitation" model orginally proposed by Stein (1965). Similar models have also been studied by Segundo et al. (1968).

In outline, the models describe a nerve cell subjected to input impulses, each of which generates a reduction in the membrane potential of the cell with a time course like a u EPSP. The background activity is introduced by a progressive depolarization of the cell. Background depolarizations and EPSPs are summated linearly. Whenever the depolarization exceeds a certain limit, the nerve cell fires an impulse, and the membrane potential is reset to its original value. Certain additional complexities could be introduced in the models, such as a time-dependent recovery of excitability after each neuronal firing. For a complete description of the models and their behavior, the reader is referred to our original paper (Walløe et al., 1969).

Such models exhibit behavior that also appears to be relevant with respect to the firing pattern of the DSCT neurons. Some features of the behavior of the nerve cells were also commonly found for the models within the range explored, such as an approximately linear increase in firing frequency with increasing input frequency and a linear increase in standard deviation of output intervals with increasing mean interval. Introduction of a time-dependent recovery of excitability or a variation in the amplitude of the EPSPs over a range considered reasonable in relation to the DSCT neurons produced only minor and trivial changes in the behavior of the models. On the other hand, to generate interval distributions and serial dependencies comparable to those of the DSCT required specific models of considerable interest. The critical feature turned out to be the time structure of the input process. With a number of afferent fibers converging onto a nerve cell, the distribution in time of the combined input activity will approximate that of a Poisson process, if independent activity in each of the input fibers is assumed. However, with a Poisson distribution of the input activity it was impossible to generate interval distributions similar to those of the DSCT neurons. The distributions obtained always contained exponential right tails. Negative serial dependencies were introduced in such models by making the speed of recovery of excitability after a neuronal firing an increasing function of the duration of the preceding interval. The effect of this mechanism was explored over a range that exceeded the range observed experimentally (Eide et al., 1969a), but it did not influence the shape of the interval distributions appreciably. Furthermore, the degree of negative serial dependency obtained in this way was much less than that found in the discharge pattern of the DSCT cells ($R_{12} \approx -0.2$ compared with -0.6 obtained experimentally). Small degrees of negative serial dependency exist, however, in the discharge pattern of several other types of neurons (Kuffler et al., 1957; Poggio and Viernstein, 1964; Goldberg and Greenwood, 1966; Firth, 1966), which may well be explained by such an accumulation of subnormality (Geisler and Goldberg, 1966).

A more realistic model, in which the input activity was generated by a number of independent "elements" with properties similar to those of the primary endings of muscle

spindles, exhibited a strikingly different behavior. The important characteristics of these "muscle spindles" were that their firing rate increased linearly with simulated "muscle length" (Matthews, 1964), and that their firing pattern at any given length was highly regular (CV = 0.04; Stein and Matthews, 1965). Even though the total input generated by a number of such "spindles" had an exponential distribution and a $CV \approx 1$, and thus was distinguishable from a Poisson process in these respects, the second-order neuron now generated output distributions closely similar to those of the DSCT neurons (Figure 4). Furthermore, with such "spindle" input there were strong negative serial dependencies in the output of the model. First-order serial correlation coefficients as high as -0.5 were found even in models with a time-independent recovery of excitability. Thus, two qualitative conclusions are reached. The particular shapes of the interval distributions and a large part of the serial dependency of the DSCT neurons appear to be due to a particular time structure of the input of these cells. The serial dependencies were generally slightly smaller in models with a realistic "spindle" input than in the DSCT neuronal discharge. With the additional mechanism of accumulation of subnormality as outlined above, the R12 increased to values observed in the DSCT neurons. Because summation of afterhyperpolarization and subnormality takes place in DSCT neurons (Eide et al., 1969a), it appears reasonable to conclude that this latter factor also contributes to their behavior.

Certain additional aspects of the behavior of the models were of some interest. As expected intuitively, the CV of the output intervals increased with increasing amplitude of the input EPSPs. In order to obtain a variability similar to that of the DSCT neurons (CV = 0.40) the EPSPs had to be approximately 50 per cent of the firing threshold of the cell. Increasing the amplitude of the EPSP also increased the slope of the input-output relationship of the model. As mentioned above, the frequency-length slopes of the DSCT neurons are approximately the same as those of the corresponding muscle-spindle afferents. Accordingly, the steady state "gain factor" can be expressed as 1/N, in which N is the number of input fibers converging onto a DSCT cell. Now, with the restriction on the size of the EPSPs required to generate the observed variability, one obtains an estimate of N required to obtain output frequencies and slopes in the observed range.

Admittedly this type of estimate is relatively crude. It was found, however, that models with 10 to 20 input "spindles" generated output frequencies similar to those of the DSCT cells. The degree of serial dependency also depended on the size of the input EPSPs and the number of input fibers. Here, again, it appeared that the models with 10 to 20 input fibers and EPSPs of half-threshold amplitude produced output intervals with serial dependencies like those of the DSCT neurons. Accordingly, the simulated models were able to generate an output activity closely approximating that of the DSCT cells with respect to interval distributions, frequency ranges, and serial dependencies, with parameters (EPSP amplitudes, number of input fibers, and recovery functions) reasonably similar to those determined experimentally.

If we accept the model, some considerations on the mode of generation of the background activity of the DSCT neurons may be justified. As we have mentioned, the background activity is usually highly regular in the absence of a primary afferent input to the cells (CV as low as 0.04). Originally, it was suggested that the background activity might be due to an excitatory synaptic input from interneurons of the spinal cord (Holmqvist et al., 1956). To account for the low rate of the background activity (10 imp/sec), the postulated EPSPs must have a correspond-

FIGURE 4 Behavior of neuronal model described in text. A and B. Distribution of output intervals at two different levels of excitation. C. Relationship between standard deviation and mean interval in the same experiment. Model consists of 15 independent "muscle spindles." Amplitude of

unitary EPSPs, 3/5 of threshold; time constant of decay, 3 milliseconds. Exponential time course of recovery after firing with time constant determined by duration of the preceding interval. (From Walløe, 1968).

ingly slow time course, but this might be explained by the assumption of a peripheral dendritic position for the interneuronal synapses. However, considered within the framework of the present model for the behavior of the DSCT neurons (Walløe et al., 1969), it was found that something between 20,000 and 60,000 imp/sec, each producing EPSPs of correspondingly small amplitude, were required to generate the background rate of firing with its high degree of regularity. This must be a highly inefficient mechanism for producing a 10 imp/sec firing rate. Alternatively, it was suggested (Walløe et al., 1969) that the background firing of the DSCT cells might be caused by a genuine pacemaker mechanism intrinsic to the cell itself.

A second prediction based on the behavior of the model concerns a group of units activated from the secondary endings of a muscle and with ascending axons among the DSCT fibers in the dorsolateral funicle of the cord. Their behavior is similar to that of the DSCT neurons activated from primary endings, except for a more regular pattern of firing (Jansen et al., 1967a). The CV of the interval distributions of their steady-state activity may be as low as 0.2. Our data on such neurons are more limited, but if it is assumed that they are activated as suggested above, the model behavior suggests that they are excited by 30 to 40 fibers generating unitary EPSPs with mean amplitudes slightly less than one-fifth of the threshold of firing.

To conclude, the study of model behavior has permitted the formulation of a reasonable hypothesis of the generation of the firing pattern of DSCT neurons, and it has given a basis for predictions of important parameters in simple neuronal chains based on their observed output behavior.

Evidence from other types of neurons indicates that their irregularity and pattern of firing may be due to mechanisms similar to those of the DSCT neurons. The observations on the eccentric cell of the Limulus eye are most instructive (Ratliff et al., 1968). In the dark-adapted state, this cell fires with a high degree of irregularity, and there are prominent random fluctuations in membrane potential as a result of the quantal nature of the light stimulus. In the light-adapted state, these fluctuations are greatly reduced, and the firing pattern of the cell is much more regular. The cell firing to a steady transmembrane outward current is characterized by a high degree of regularity (Ratliff et al., 1968). Calvin and Stevens (1968) have shown that the firing pattern of motor neurons is explained by the synaptic noise recorded in the same cells. But even though it appears that simple models of the synaptic excitation, such as the model proposed by Stein (1965), may be sufficient to explain the behavior of many simple neurons, more complicated situations can easily be visualized. For instance, in a nerve cell with multiple spike-generating regions the mode of functioning might be entirely different.

An assessment of transfer efficiency

Considerable importance is attached to the development of a quantitative measure of the efficiency of synaptic transmission (Perkel and Bullock, 1968). Information theory as developed by Shannon (1948) provides a possible approach, and its application to nerve signals has been explored by Stein (1967b). The application of information theory requires a measure of the degree of correspondence between input and output signals. Frequency coding is assumed and appears reasonable (Figure 1D). At the second-order level of the DSCT, the input is the mean frequency of the spike trains of the primary afferent fibers. The mean frequency, measured over a short period of time, of the second-order neuron represents the output. The problem then is to determine the distribution of output signals for any possible input signal. Different methods have been employed on the signals of DSCT neurons (Walløe, 1968). Because it has not been possible to measure the input and output simultaneously, all assume that the firing irregularity of the second-order neuron to a given steady input signal is representative of the uncertainty of the output signal to this input. Therefore, the problem is reduced to how accurately the mean frequency of firing of the second-order neuron can be determined. Because of the irregularity of firing, this accuracy obviously increases with increasing "observation time."

One method was similar in form to that of Werner and Mountcastle (1965), and was based on the estimation of the transinformation in an input-output matrix of contingent probabilities. The second method depends on the increasing accuracy of the estimate of mean frequency with increasing observation time. For the details of the methods employed, the reader is referred to the original publication (Walløe, 1968).

Both methods gave transinformations increasing logarithmically with observation time, and qualitatively similar results were obtained by both. Some quantitative differences can probably be accounted for by the various approximations involved.

Certain findings were of particular interest. It appeared that the transinformation decreased significantly (from 1 to 1.5 bits at any observation time) if the discharge trains were read in a randomly permutated sequence instead of in their original order. The DSCT transmission accordingly provides an example of the possible importance of the detailed time structure of spike trains for the efficiency of signal transmission, even when the signal is read as a frequency code.

The further question of a possible physiological significance of this property of the discharge pattern requires, first, that the receiver of the signal reads the activity of only one such nerve fiber. If several fibers with independent activity converged onto the third-order neuron, the time structure of each fiber's signal would largely be lost. Therefore, it appears significant that the DSCT axons terminate in the rather unique synaptic structures called cerebellar glomeruli. Each glomerulus consists of the processes of several third-order neurons, all ending in relation to the end bulb of only one mossy fiber (Ramón y Cajal, 1911).

For the DSCT transmission, input as well as output signals are reasonably well known. It is, therefore, possible to make rough estimates of the amount of information that is lost during the synaptic transfer. Stein (1967b) has derived expressions that are convenient for this comparison, and his formulas give results that are reasonably close to those of the methods outlined above. With an observation time of 200 milliseconds, each primary afferent fiber transmits about 4.6 bits if one assumes a frequency range of 10 to 80 imp/sec, like that experimentally observed. The main reason for the relatively high information content is the great regularity of firing of these primary afferent fibers (CV = 0.04; Stein and Matthews, 1965). About 15 primary afferent fibers converge onto each second-order neuron. They all carry the same kind of information (i.e., muscle length), but are firing independently of one another, so the second-order neuron will receive a quantity of information equivalent to that of a 15-times-longer record of the signal from one fiber. This is estimated to about 6.6 bits in 200 milliseconds. The signal of the second-order neuron contains about 3.0 bits over a frequency range equal to that of each input fiber. Accordingly, about half of the information is lost during the synaptic transfer.

The information content of the second-order signal is even smaller than that of each primary afferent fiber. Two points are worth mentioning in this connection: first, that some 30 per cent of what is transmitted is caused by the particular time structure of the second-order signal and, second, that the greater part of the loss is caused by the convergence of several primary afferent fibers. The estimation that the total content of the input is equal to a 15-timeslonger record of one primary afferent assumes that the regularity of firing is preserved in each fiber. Alternatively, if the input signals are regarded as randomly distributed and covering a frequency range of 15 times that of each input fiber, the information content of the total input is approximately the same as that of the second-order neuron.

It is interesting that this high cost of synaptic transmission is found in a highly effective system like the DSCT. The justification for the introduction of synapses at this high cost must be the possible control of the transfer process, for instance by inhibition (see below).

The present estimates consider the transmission to each second-order neuron only. There is some justification for this from the evidence that the second-order signals are read individually (see above). When the system is considered as a whole, however, the information lost during transmission from first- to second-order neurons is less, because each primary afferent fiber presumably projects to several second-order neurons. The degree of divergence at the first- to second-order level is unknown at present.

By comparing psychophysical estimates of stimulus intensity and the signals of primary afferent fibers from cutaneous receptors, Werner and Mountcastle (1968) found that there is sufficient information in the signal of a single afferent fiber to account for the magnitude estimates. In view of the appreciable loss of information even in the powerful DSCT synapses, it can safely be suggested that human behavior can be explained only if one assumes the participation of a considerable number of neurons at all stages of the relevant pathway. The quantitative correspondence between subjective stimulus estimates and the signal of a single primary afferent (Werner and Mountcastle, 1968) may therefore be largely fortuitous.

The effects of inhibition

A further illustration of the usefulness of the model appears when the effects of inhibitory inputs on the firing pattern of DSCT neurons are analyzed. Inhibition of neurons relaying signals from the anterior tibial muscle and the flexor digitorum muscle was obtained regularly by repetitive electrical stimulation of group I afferent fibers in the gastrocnemius-soleus nerve (Jansen et al., 1969). An example is shown in Figure 5A. After an initial transient, the inhibition is maintained for the entire duration of the inhibitory input, which permitted a study of the effect of "steady-state" inhibition on the firing rates and discharge pattern of the DSCT neurons.

Two contrasting effects were observed in different neurons. For some, the inhibitory effects measured as the reduction in firing frequency were independent of the degree of excitation of the cells (Figure 5B). These neurons showed no appreciable change in firing pattern, as evidenced by their interval histograms, CVs (Figure 6C), and serial dependencies (Jansen et al., 1969). In other neurons, a constant inhibitory input caused increasing reduction in firing frequency at higher levels of excitatory drive (Figure 5C). This type of behavior was associated with an increased regularity of firing (Figure 6D) and a reduced serial dependency of the discharge. However, all degrees of transitions were found between these two extremes of behavior. Thus, there was nothing in the experimental data to suggest that basically different mechanisms might be involved.

For the discussion of possible synaptic mechanisms underlying the inhibitory effects, our model of the DSCT neuron is accepted tentatively. Postsynaptic (Eccles et al., 1961; Hongo and Okada, 1967) as well as presynaptic

FIGURE 5 Inhibition of transmission in second-order neurons by stimulation of peripheral nerves. A. Sample record (7 seconds cut out from middle of continuous record). Neuron activated by steady extension of anterior tibial muscle. Period of inhibitory repetitive stimulation of triceps nerve indicated by line. B. Firing frequencies during maintained inhibition, Fi (ordinate), plotted against firing frequencies in control period, Fe (abscissa). Unit

activated by varying degrees of maintained stretch of flexor digitorum longus muscle and inhibition elicited by 100-persecond stimulation of triceps nerve. C. As B, another neuron. (A, B, and C from experiments reported by Jansen et al., 1969.)

(Eccles et al., 1963) inhibition of DSCT neurons after activation of spinal nerves have been described. To consider the simplest situation first, presynaptic inhibition should, by definition, reduce the size of the EPSPs without altering the properties of the postsynaptic neuron. In the model, the result would be an increased regularity of firing and a linear reduction in the slope of the input-output relation of the neuron. Accordingly, a presynaptic mechanism cannot explain the inhibition with an unchanged slopeconstant and firing pattern. Furthermore, the inhibitory input regularly terminated the background firing of the DSCT neurons (Jansen et al., 1969), and this effect cannot be caused by presynaptic inhibition, as the background firing appears to reflect inherent pacemaker activity of the second-order neurons (see above).

Postsynaptic inhibitory mechanisms can, on the other hand, explain the observed effects. A postsynaptic inhibition, which acts predominantly by hyperpolarizing the cell, should not change the size of the EPSPs appreciably (Eide et al., 1969a). Accordingly, the firing pattern and the slope of the input-output relation should remain unchanged. If, however, the inhibition is associated with an increased conductance that reduces the input impedance of the cell, the amplitudes of the EPSPs will be reduced in proportion to the reduction in input impedance. Consequently, input-output slopes will be reduced, and the firing pattern will be changed in the observed direction. Thus, the simplest explanation for the observed inhibitory effects is that they are due to a postsynaptic inhibition causing various degrees of inhibitory "shunting" in the different DSCT neurons. If the axons of the inhibitory interneurons involved terminated more or less peripherally on the dendrites of DSCT neurons, such effects would be expected, which is in line with Rèthelyi's recent anatomical description of Clarke's column synaptology (1968). The postsynaptic nature of the inhibition is also suggested by the similar effects of the inhibition of transmission evoked from the somatosensory cortex (Jansen et al., 1969). This inhibition has been shown to be entirely postsynaptic (Hongo and Okada, 1967).

The observations on inhibition of signal transmission in the DSCT illustrate two important inhibitory effects. The

FIGURE 6 Firing patterns during maintained inhibition. A and B. Interval distributions of neuron, showing more regular firing during inhibition. A. Distribution during maintained activation of neuron by 50-gram-weight load on tibialis anterior tendon. B. Same cell as A. Excited by a 150-gram load on muscle tendon and inhibited simultaneously by repetitive nerve stimulation. Mean frequency

of firing is approximately the same as in A. Inhibition caused a reduction in firing frequency of 29 imp/sec from preceding control period. C, D. Data from two different units. Scatter diagrams of standard deviation against mean intervals during control periods (closed circle) and during inhibitory nerve stimulation (open circle). (Data from Jansen et al., 1969.)

reduction of input-output slope during inhibition represents a reduction of the "gain" of transmission. Inhibition with maintained input-output slope, on the other hand, does not affect the gain. Comparable effects have been obtained for both the peripheral inhibition of crayfish receptors and lateral inhibition in *Limulus* eyes (Terzuolo et al., 1968). The behavior of motor neurons is also of interest in this connection. Postsynaptic inhibitory inputs always reduce the frequency of firing of these cells, usually without any change of slope of the input-output relation (Granit and Renkin, 1961; Granit et al., 1966), even though the inhibitory input commonly reduces the input resistance of the cell. According to Kernell (1969), the explanation is that the afterhyperpolarization is the dominating mechanism that controls the firing frequency of motor neurons.

Conclusions

The signal transmission of the DSCT exhibits several properties that may also be relevant for other central nervous pathways. The most important is the wide range of linearity of transmission from first- to second-order neurons. This width of range is due to the linear current-frequency relation of the DSCT neurons and to the linear summation of their excitatory synaptic input. These properties and the time structure of presynaptic activity determine the firing pattern of the postsynaptic neuron. The particular firing pattern generated may significantly improve the efficiency of information transfer. Postsynaptic inhibitory mechanisms, which partly hyperpolarize and partly reduce the input impedance of the second-order neurons, explain inhibitory effects on the signal transmission. With its relatively simple organization and experimental accessibility, the DSCT appears to be a suitable system for further analysis of signal transmission in the central nervous system.

Some Principles of Synaptic Organization in the Visual System

OTTO D. CREUTZFELDT

Nobody would attempt to describe and define within any practical amount of space the general concept of analogy which dominates our interpretation of vision. There is no basis for saying whether such an enterprise would require thousands or millions or altogether impractical numbers of volumes. Now it is perfectly possible that the simplest and only practical way actually to say what constitutes a visual analogy consists in giving a description of the connections of the visual brain.... It is ... not at all unlikely that it is futile to look for a precise logical concept, that is, for a precise verbal description, of "visual analogy." It is possible that the connection pattern of the visual brain itself is the simplest logical expression or definition of this principle.

John von Neumann

THE PRESENTATION OF the following material and the discussion of some of its implications may be considered out of place within the context of "Communication and Coding in the Nervous System," but I selected this material with the notion that principles of such coding are best demonstrated by analyzing the principles of connectivity in the nervous system. I believe that the thoughts of John von Neumann, quoted above, express very well the approach I favor in this context. One of the main aspects of coding within the nervous system is the spatial arrangement of its elements, the relations between them, and the combination of signals arriving at any given ganglion cell and at groups of ganglion cells from the different input sources of the periphery. This combination of inputs is the reason for the apparently increasing complexity of response characteristics and stimulus parameters of neurons at the higher levels of the nervous system, and emphasizes the intimate link between structure and function. A further reason for this presentation is that one of our aims should be to discover principles of input combinations based on mechanisms that force some types of neurons into excitatory or inhibitory contacts with certain neurons but not with others. My aim is to point to some of these principles within the visual system, although I realize that such an

analysis of the "functional Bauplan" of the nervous system is only at its starting point. Therefore, this aspect may be taken mainly as a stimulus for further research.

One of the basic electrophysiological principles of information transmission is that the output discharge frequency of a ganglion cell is linearly related to the current passing across the soma membrane (Hodgkin, 1948; Jansen and Walløe, this volume.) This statement is limited, however, because the excitability of a ganglion cell may change during a longer-lasting suprathreshold excitation (adaptation: Creutzfeldt et al., 1964; Granit et al., 1963). Furthermore, nonlinearities in the neuronal input-output relation may result from nonlinear properties of postsynaptic potential (PSP) summation and variable anatomical relationships between the input area (dendrite) and the trigger zone.

Methods

The experiments were done on cat retina, lateral geniculate body, and visual cortex (area 17). In all cases the animals were fixed in a head frame and faced a tangent screen placed 1 meter from the eye. The pupils were dilated with synephrine-atropine and the corneas were covered with contact lenses of 0.00, +1.0 or +1.5 diopter. We conducted the retinal experiments under a continuous N₂O-anesthesia, most of the geniculate experiments after a single Nembutal injection of 30 mg/kg, and the cortical experiments after ether anesthesia. In all experiments we anesthetized the fixation points and wounds locally. A Flaxedil-curare mixture was applied continuously through an intravenous cannula. Body temperature and artificial respiration were controlled carefully.

Retinal activity was recorded from single optic-tract fibers with stereotactically introduced steel or tungsten electrodes. Geniculate and cortical units were recorded with glass micropipettes in an intracellular or "quasi-intracellular" electrode position. In all cases, only the skull and the dura were removed, at the place of electrode introduction, and during recording the hole in the skull was covered around the electrode.

Light stimuli of varying form, intensity, and exposure

OTTO D. CREUTZFELDT Department of Neurophysiology, Max-Planck-Institute for Psychiatry, Munich, Germany

frequency were projected on the tangent screen. Such projection could be done by computer-controlled stimulators and with on-line computer analyses of the responses during the experiments, or with a separate programing device and off-line analysis via tape recording. On-line analysis was done with an IBM 1130 system developed in our laboratory (Färber and Probst, 1968); off-line analysis, either with the IBM 1130 or with a CAT 1000. Photographic recordings could be taken from the tape.

Results

FUNCTIONAL ORGANIZATION AT THE RETINAL LEVEL The retina performs linear and nonlinear operations. I describe some of these and, by using appropriate experiments as examples, try to localize them within the different layers. Figure 1 is a schematized drawing of the different levels of the retina. The structure, as revealed by anatomical work (Polyak, 1941; Dowling and Boycott, 1966; Boycott and Dowling, 1969; Brown, 1965; Brown and Major, 1966; Leicester and Stone, 1967), suggests that the activity of many receptors is integrated by one bipolar cell, and that several bipolar cells converge on one ganglion cell. Only relatively few bipolar and ganglion cells have an anatomical arrangement compatible with the one-to-one connection between a single receptor and a single ganglion cell as found in the primate retina (Boycott and Dowling, 1969). We have never recorded from cat ganglion cells, the properties of which suggested such a one-to-one relationship with only one receptor. Hence, all ganglion cells whose properties are discussed sum activity from many receptors. In what follows, I am assuming that more than one bipolar cell is in contact with each ganglion cell.

The summation area of a ganglion cell is called its receptive field center (RFC). It is surrounded by an area (the receptive field surround [RFS]) the stimulation of which leads to an effect that is the reverse of the center-stimulus effect. Excitation of receptors within the RFC may lead to an excitation of the underlying ganglion cell (on-center cells) or to an inhibition (off-center cells). In the latter case, the darkness after the light stimulus leads to an acceleration.

Let us assume that the size and shape of a ganglion cell RFC are determined by the distribution of its dendrites. Anatomical studies show that the distribution is in one plane

FIGURE 1 Schema of the retina. The integrative and transfer functions of the different levels are described at right. Horizontal arrows: Spatial integration, interaction, or both. Ver-

tical arrows: Input into and transfer through the various elements. (See text.)
(Figure 2A) and that the dendritic "domains" are almost round (Brown, 1965; Brown and Major, 1966; Leicester and Stone, 1967), with diameters of between 80μ and 800μ , as determined from Golgi impregnations. These correspond to visual fields of about 0.5 degree to 4 degrees in diameter (Leicester and Stone, 1967).

Let us further assume that each receptor that lies above a dendritic branch of an on-center ganglion cell has an excitatory contact with the latter (through a bipolar cell, of course), and that synapses are distributed nearly uniformly along the dendrites. The sensitivity of that ganglion cell to a small stimulus within its RFC should be determined not by the total number of receptors illuminated but by the number of illuminated receptors that are in contact with the cell (Figure 2B-D). The spatial sensitivity of retinal ganglion cells should then be a function of the spatial density of their dendrites.

If one measures the area density of ganglion-cell dendrites within small areas at variable distances from the soma, one gets curves that are similar to, although somewhat more irregular than, the sensitivity distribution as determined in the physiological experiment (Figure 3). The differences can be corrected either by introducing a factor which takes into account the electrotonic attenuation of excitatory postsynaptic potentials (EPSPs) along the dendrites, or by assuming that each bipolar cell makes several contacts with one dendritic tree within the area of the domain of bipolar branching $(20\mu - 40\mu$ in diameter, Leicester and Stone, 1967), or by both. At the periphery of the domain of a dendritic tree, only few or one contact with the bipolar cells situated there can be expected. The effect of electrotonic attenuation can be estimated by the weighting factor $g(x) = \frac{1}{\cosh x/\lambda}$ in which x is the dendritic length and λ the length constant (Creutzfeldt et al., 1968). For a dendritic length constant of 100μ -150 μ , the curves expected theoretically, based on histology, are virtually identical to experimental sensitivity curves (Figure 3, page 634).

This model can be tested. If a logarithmic summation of light quanta in the receptor-bipolar cell complex and a linear summation of excitation at the ganglion cell are assumed, the response (R) of the ganglion cell is related to the intensity (I) of a stimulus at different locations within the receptive field by $R = c \cdot f(1/r) \cdot \log I$. The factor f(1/r) depends on the dendritic density and the electrotonic attenuation as a function of the stimulus distance (r) from the RFC middle. In a semilogarithmic plot, the slope of the response-intensity curves should then vary according to the factor f(1/r). Figure 4 shows that within a distance of 1 degree from the middle of the receptive field the slopes are identical, indicating only small changes of f(1/r) in this part of the RFC. At greater distances the curves are more horizontal, indicating a decrease of f(1/r).

As suggested by the PST histograms and as discussed else-

where, this effect can hardly be due to increased lateral inhibition from the surround. It agrees with the model and indicates fewer excitatory contacts at the periphery of the RFC than within its center. The plateau in the middle of the RFC (which is also found in the threshold experiments of Cleland and Enroth-Cugell, 1968) supports the view that here the overlap of bipolar branches compensates for electrotonic attenuation. The dendritic density in this central part of the RFC does, in fact, change relatively little, as shown in Figures 2 and 3.

If the ganglion cell should sum excitatory inputs linearly, one would expect that the response to round stimuli concentric to the RFC would be identical to the sum of responses to small spots of light within the larger stimulus area. They should then be proportional to the spatial sensitivity distribution along the radius. Such is, in fact, the case for stimuli that are close to threshold (Cleland and Enroth-Cugell, 1968) and for weak suprathreshold stimuli, as shown in Figure 5 (circles in A). The plateau of the sensitivity curve of most neurons near the center of the RFC explains that, for a restricted central area of the receptive field, Ricco's law (I \times A = constant) is applicable. But if stronger stimuli are used, the ganglion-cell responses are considerably smaller than those calculated (Figure 5, page 636, triangles in A), indicating a nonlinear summation of excitation signals within the ganglion cell. One can investigate this result further by recording the responses to stimuli of variable diameter and intensity.

If the excitatory signals arriving at the ganglion cell were proportional to log I and were summed up linearly, the responses (R) should be of the form $R = f(A) \times \log I$. As in the first experiment, the slope of the intensity-response curves in the log plot should change considerably with the stimulus area (A). But such is not the case, and the slopes rise only slightly with increasing area (Figure 6, page 637). A completely parallel course of the intensity-response curves would suggest a logarithmic summation of incoming signals in the ganglion cell, whether they result from increase of area or increase of intensity. The ganglion-cell response would correspond to $R = c \times \log(I \times A) = c \times$ $(\log I + \log A)$, which would imply a linear signal transmission in the receptors. The light flux $I \times A$ for evoking equal responses at different intensities and stimulus areas should then also be equal. Consequently, Ricco's law would also be applicable to suprathreshold stimuli.

Such a possibility is also excluded. The equal-response lines (broken lines in Figure 6), which would be parallel to the 45-degree lines (that correspond to log I + log A = constant), become more horizontal as the responses become larger, which indicates a higher efficiency of a low-intensity stimulus which covers a large area, than that of a highintensity stimulus which covers a small area. Hence, the receptor-bipolar complex is more sensitive at low than at

FIGURE 2 Dendritic density of retinal ganglion cells. A. The dendritic field of a rat retinal-ganglion cell, seen from above. The numbers on the dendrites indicate the depth in microns from the inner retinal surface. Golgi-Cox preparation (Brown, 1965). B. Dendritic field of cat retinal-ganglion cell (Brown and Major, 1966). A grid is projected over the dendritic tree. Each square corresponds to the area of about four receptors. Whenever a dendrite passes through a quarter of one square (receptor), a dot is made. The small and large circles indicate the retinal areas covered by light spots

in the following experiments. C. Number of "dendrite-receptor crossings" (ordinate, see B) which are covered by the small circles (simulated light stimuli) at different distances from the center of the receptive field (abscissa). Solid line: Simulated "stimuli" along the horizontal axis. Broken line: Simulated stimuli along the vertical axis. D. Cumulative number of dendrite-receptor crossings (ordinate) covered by disks (stimuli) of increasing radius (abscissa). The straight line represents the increase in stimulus area. (From Creutzfeldt et al., 1968.)

FIGURE 3 Response profile (A, B) and dendriticdensity distribution across the receptive field of retinal ganglion cells. A, B. Responses of retinal ganglion cells to small suprathreshold spots of light (diameter 10 min \measuredangle) shone into different parts of the receptive field along one axis of the receptive field. Ordinate: Discharges per second during the first 120 milliseconds of the response. A. On-center neurons. B. Off-center neurons. Below each set of curves are indicated the mean RFC diameters of 19 retinal oncenter and 13 retinal off-center neurons, as determined from the sensitivity curves. C-F. The dendritic-density distribution of four retinal ganglion cells as determined by the method explained in Figure 2B and C. The diameter of the simulated stimuli corresponds to that of the stimuli used in the experiments of A and B. Distance from middle of RFC is on the abscissa (values in F). The counts were done on Golgi preparations of retinal-ganglion cells (C-E), published by Brown and Major (1966), and (F) Leicester and Stone (1967). The upper curves in each diagram represent the original counts of dendritic receptor crossings; the two inner curves are the result of weighting the counts according to dendriticlength constants (λ) of 200 and 100 μ (see text). (From Creutzfeldt et al., 1968.)

COMMUNICATION AND CODING IN THE NERVOUS SYSTEM

634

SYNAPTIC ORGANIZATION IN THE VISUAL SYSTEM 635

high light intensities, and thus does not transmit the intensities linearly. At the largest stimulus diameter, the equalresponse lines turn upward toward higher light intensities, because the peripheral parts of these large stimuli already cover receptors that are not in excitatory contact with this ganglion cell.

The spatial sensitivity distribution and the area summation experiments suggest more than one mechanism for nonlinear signal summation within the RFC: (1) nonlinear signal summation in the receptors; (2) nonlinear sensitivity distribution of ganglion cells because of their dendritic geometry; and (3) nonlinear summation of excitatory signals in the ganglion cell. If our earlier statement on linear transmission of ganglion cells is also valid for retinal ganglion cells, we would have to locate the nonlinearity in the dendrites: simultaneous excitation of many neighboring synapses might lead to conductivity changes of the dendritic membrane and thus to nonlinear input-output summation properties. Another possibility of nonlinear transmission within retinal ganglion cells was discussed by Stone and Fabian (1968), who assumed that the relative refractoriness of the initial segment increases the threshold for as long as 20 milliseconds. As yet we have had no indication that an active inhibitory process peripheral to the ganglion cell is responsible for the nonlinear signal transmission in the RFC, as was suggested by Büttner and Grüsser (1968).

So far, I have discussed retinal nonlinearities caused by retinal-cell geometry and by nonlinear summation of excitatory signals in receptors and ganglion-cell dendrites. A further nonlinearity of spatial and intensity transfer is brought about by lateral inhibition from the receptive-field surround. I shall not go into the problem of lateral inhibition and contrast perception, as this is discussed elsewhere (Reichardt, this volume; for further information, see

FIGURE 5 Experimental responses of a cat retinal-ganglion cell to stimuli of variable diameter (closed symbols) compared with expected responses (open symbols) calculated from the sensitivity distribution in different parts of the receptive field (figure on right). A. Responses (discharge rate during first 100 milliseconds of response, ordinate) as function of stimulus diameter (in minutes of arc, ordinate) at low intensity (closed circles) and high intensity (closed triangles). The two intensities ΔI are indicated on the side. Open circles: Expected responses for low intensity as calculated from the sensitivity distribution shown in B and from the response to the smallest spot. Open triangles: Expected

responses to high-intensity stimuli. The response to the largest stimulus is taken as the basis for calculation of the lower curve, and the response to the smallest spot is taken as the basis for the upper curve. B. Sensitivity distribution as determined by responses (ordinate, discharge rate during first 100 milliseconds of response) to small spots (10 minutes in diameter) shone into different parts of the receptive field (abscissa, distance from middle of RFC). The diagram shows the average of four stimulus series along different axes through the receptive field. This explains the regular "pyramidal" shape of the sensitivity distribution.

FIGURE 6 Effect of increase of stimulus intensity and size on response of a retinal on-center ganglion cell of cat. These response-intensity plots are for spots of light with various stimulus diameters concentric to the RFC. Each open circle is the average from 10 stimulus applications (discharge rate during first 50 milliseconds of response). Abscissa is the log of the intensity, and the discharge rates are plotted against variable linear ordinates the zero points of which, for each stimulus size, are at the intersection of the broken lines with the vertical log-A axis. This intersection also indicates the logarithm of the surface (log area) of the stimulus with which the connected stimulus-response curve was made. The numbers 20 to 260 are discharge rates. The thin lines

connecting equal abscissa and ordinate values represent the log I + log A = constant, and therefore respond to Ricco's law (I \times A = constant). The thicker lines, which have negative slopes and go from 40 to 260 per second, connect equal responses of the different stimulus series. These lines run roughly parallel to log I + log A = constant for only small responses (e.g., 40 and 60), but not for larger ones (e.g., 160 and 180). Those, being more horizontal, indicate that at larger diameters less intensity is needed to produce a given response than at small diameters. Only at the largest diameter (top curve) do the equal response curves turn up again because the stimulus is larger than the RFC.

Ratliff, 1965). Another effect of lateral inhibition in the retina is that it controls the background activity of on-center neurons at various light intensities. If diffuse light is shone on the retina, the discharge rate of on-center units increases and that of off-center units decreases only when relatively low intensities $(10^{-4} \text{ to } 10^{-5} \text{ cd/m}^2)$ are used, i.e., only in the scotopic and lower mesopic range. At higher intensities, many on-center cells are slowed, whereas only a few are accelerated up to values of 10^{-3} to 10^{-2} cd/m² (candella per square meter) and then level off. This variable behavior results from the strength of the inhibitory surround, which, if strong, will slow the neuron discharge. Because on-center

neurons increase their maintained discharge rates only up to intensities of 10^{-2} cd/m² and decrease at greater intensities and because most off-center units are completely inhibited above a light intensity of 10^{-3} to 10^{-4} cd/m², a decrease of the mass activity in the optic tract results, as Arduini and Pinneo (1962) observed by using large electrodes. This makes one doubt that the perception of ambient light is transmitted by the increased firing frequency of a large neuronal population.

Finally, if retinal transfer functions are discussed, the regulation of retinal sensitivity due to adaptation must be included. In the photopic range, the adaptation is mainly photochemical and is proportional to the amount of bleached photopigment. In the scotopic and mesopic range, a neuronal adaptation mechanism has been proposed (Rushton, 1965). It is assumed that the excitation of the receptors is pooled and changes the gain of the receptor-bipolar signal transmission. Recent measurements of this gain control showed that it is not proportional to the intensity I of the adapting light, but to Iⁿ (with a mean value of n = 0.6; Sakmann and Creutzfeldt, 1969). In the scotopic-mesopic range, the sensitivity of the retina does not, therefore, decrease in proportion to I as implied in the Weber-Fechner law ($\Delta I/I = \text{constant}$), but to I^{0.6}. The Weber-Fechner relation is found only in the photopic range with photochemical adaptation.

The localization of the neuronal adaptation mechanism can only be approximated: if one plots the response of a ganglion cell to small light stimuli shone into the center of the receptive field against the logarithm of intensity, the result is a straight line over an intensity range of about 1.5 log units. It levels off at the lower and upper limits because of the retinal threshold sensitivity and the maximum discharge rate that a ganglion cell can maintain for a certain length of time (initial 50–100 milliseconds of the response). The curves obtained at different (scotopic and mesopic) adaptation levels run parallel, but the intensity range of the ganglion-cell response from threshold to the upper limit (1.5 log units) is independent of adaptation (Figure 7). The response (R) versus intensity (I) curves are described by R $= a \times \log I$; a determines the slope of the curves and is independent of the adaptation level. Therefore, the gaincontrol mechanism must be situated peripherally from-or in the same-elements in which the logarithmic summation of light intensity takes place. If the log transformation of intensity takes place in the receptors, adaptation must directly influence the gain of the receptors. It could be localized either within the receptors themselves or in such a way that it could change receptor sensitivity by a feedback control through the horizontal cells. But if the nonlinear summation of the retina is largely a function of the ganglion cells, the gain-control mechanism may be localized anywhere between the receptor and the input site of the ganglion cell.

Figure 7 also demonstrates the improvement of relative sensitivity at higher adaptation levels. Two lines are drawn through the responses at equal $\Delta I/I$ fractions. If the sensitivity $\Delta I/I$ would not change, the lines should be parallel to the abscissa, but, in fact, they show an inclination.

From the experiments reported, it is clear that the retina is a nonlinear signal transmitter, although under certain conditions and within certain limitations, linear behavior can be demonstrated (Hughes and Maffei, 1966). I have tried to demonstrate how the different components of these nonlinearities might be analyzed, and even tentatively be localized, in the different levels of the retina, as shown in Figure 1. As yet, we cannot localize some mechanisms satisfactorily. Whether this is because of an incorrect model or a combination of similar mechanisms at different levels must be determined by further experiments.

Synaptic organization of transmission in the lateral geniculate body (LGB)

Synaptic organization in the LGB differs from that in the retina. Here, the retinocortical flow is interrupted by relay cells, and retinocortical impulses come under the influence of activity from other brain structures, as well as under some inhibitory influence from the contralateral retina. I do not discuss this latter aspect here (for further references, see Creutzfeldt and Sakmann, 1969); we shall deal mainly with the organization of the retinocortical relay.

Receptive fields of geniculate cells differ little from those of the retina (Hubel, 1963), especially the receptive-field centers, which, in our experience, are the same size as those of retinal ganglion cells. If one records intracellularly or quasi-intracellularly from geniculate relay cells, one can isolate single EPSPs (McIlwain and Creutzfeldt, 1967). These EPSPs are of large amplitude (up to 5–10 mV) and of equal shape. Their amplitude variation is within the limits

FIGURE 7 Intensity-response plots of a retinal on-center ganglion cell at different adaptation levels. The response (ordinate) is the discharge rate during the first 100 milliseconds. The intensity of the test spot is shown on the abscissa. The spot (10 minutes in diameter) is shone into the middle of the RFC. The numbers on the responseintensity curves indicate the exponent of the brightness of the adapting light (-5 means adapting light = 10^{-5} cd/m²). The two lines through the plots are drawn through points of equal $\Delta I/I$. If $\Delta I/I$ results in a constant response (Weber's law), the lines should be horizontal. See text for further details. (After Sakmann and Creutzfeldt, 1969).

that can be attributed to the fluctuations of the membrane potential (see Figure 8). Their frequency during spontaneous and evoked activity is equal to that found in single retinal ganglion cells under the same conditions. From these and other findings, we concluded that one geniculate relay cell receives its specific retinal excitatory input from only one optic-tract fiber (Creutzfeldt, 1968a; Singer and Creutzfeldt, 1970). Because optic-tract fibers divide into several branches before they terminate in brushlike endings (Guillery, 1966), the implication is that—at least in the foveal and parafoveal area—one tract fiber must innervate several relay cells and that the number of relay cells should be greater than the number of optic-tract fibers (for further discussion, see Singer and Creutzfeldt, 1970).

Electrical stimulation of the optic tract reveals that oncenter as well as off-center fibers primarily excite LGB relay cells (Fuster et al., 1965). This excitatory contact must be very powerful, as suggested by the large amplitude of the EPSPs. The anatomical basis of such synaptic connections has been described by Szentágothai et al. (1966). The significance of such a synaptic organization for information

transmission is obvious. The duration of one EPSP is about 20 milliseconds (with an early linear decay), and the threshold of the cell is about twice the amplitude of an EPSP. Therefore the probability of a threshold depolarization depends on the EPSP rate and pattern, as is shown schematically in Figure 9, in which a random discharge rate of the afferent fiber (input) that elicites the EPSPs is assumed. Such a distribution is found in the optic tract (Herz et al., 1964). The input-output relationship depends on the mean discharge rate of the afferent fiber and improves as the latter increases (Figure 9A-C). Also, the transmission latency decreases with the discharge rate (Figure 9D). Above a maximal input rate, the output frequency of the cell is limited by its own maximal firing rate. Therefore, the transinformation of such a transmitting system is optimal at an intermediate discharge rate of the afferent input. The synaptic "noise" at a lower frequency is not transmitted.

The receptive field of geniculate relay cells has a powerful inhibitory surround, both because of the relative lack of excitation during illumination of the surround area of the retinal afferent fiber and because of an active inhibition

FIGURE 8 EPSPs from one optic-tract fiber in a lateral geniculate relay cell (on-center cell). Cat, Nembutal. Inset shows original record from a quasi-intracellular recording. The horizontal line through the record indicates the resting potential (membrane potential when no PSP activity is present). Diagram: Amplitude of EPSPs (ordinate) plotted

against relative membrane potential (abscissa) at the start of the EPSP. The membrane potential was measured relative to the resting level as shown in the record. Closed circles, EPSPs during darkness; crosses, EPSPs during light stimulation. (Courtesy of Dr.W. Singer.)

FIGURE 9 Schematic drawing of input-output relation of a cell that receives its excitatory input from one fiber. It is assumed that the fiber discharges at irregular intervals and that the duration of the EPSP is short in relation to the average interval when the discharge rate of the fiber is low

(A), but long compared with the average interval at highdischarge rate (C). D. Input:output latency as a function of discharge rate of the fiber response. (From Creutzfeldt, 1968b.)

(McIlwain and Creutzfeldt, 1967). An analysis of this inhibitory input showed that LGB on-center cells are inhibited by off-center neurons and off-center cells by oncenter neurons (Singer and Creutzfeldt, 1970). This conclusion is based mainly on the amplitudes and latencies of the inhibitory and excitatory components, seen after focal stimulation in different parts of the receptive field. This analysis suggested the model of LGB synaptic organization that is shown in Figure 10. It is not clear whether the inhibitory input comes directly from retinal on-center or offcenter fibers or from geniculate relay cells via recurrent collaterals. Electrical stimulation of the optic radiation shows that recurrent inhibition exists in the geniculate, and the computer simulation of the geniculate responses gave the best results if recurrent inhibition was assumed. But evidence is not yet sufficient for hypothesizing exclusively a recurrent mechanism. A simulation is shown in Figure 11.

The model suggests an important principle of synaptic organization in the LGB. On-center cells of the LGB receive excitatory input only from on-center fibers of the optic tract and inhibitory input only from the off-center fibers, which implies a high degree of specificity in the selection of afferent connections. The same is true of off-center cells, which receive excitation exclusively from off-center fibers and inhibition from on-center fibers. This specificity suggests that the contact of a geniculate relay cell with one type of afferent fiber (on or off) may determine the cell type and therefore render it selective for further contacts with fibers (interneurons or recurrent collaterals) of another type. A chemical determination of this selectivity could be an attractive approach for verification.

It is not obvious how this synaptic organization of the LGB aids in information transmission. Some functions may be discussed. The active inhibition guarantees a cut-off of nonspecific, and perhaps corticofugal, excitatory

FIGURE 10 Schematic drawing of the synaptic organization in the LGB. A. On-center cell. B. Off-center cell. Top: Sketch of the assumed synaptic connection. The on-center cell is shown receiving excitation from one retinal on-center ganglion cell, and inhibition from a number of off-center ganglion cells. Possible inhibitory interneurons were omitted for simplicity. *Mutatis mutandis* for the off-center LGB cell in B. The black spots in the receptive field of the LGB cells indicate the positions of light stimuli shown below. Lower part: Responses of the assumed input fibers. A. Excitation of the on-center fiber leads to EPSPs; excitation of off-center fibers leads to IPSPs. The approximate sum of EPSPs and IPSPs at the different positions of the stimulus is shown in the smooth curves below the semischematic drawings of fiber activity. B. Off-center cell. Activation of the retinal off-center fiber leads to EPSPs; activation of oncenter fibers to IPSPs. Bottom: Light stimulus. The vertical lines show the latencies of the various responses (shortlatency excitation at light on in A and at light off in B; short latency inhibition at light off in A and at light on in B; and so on). (From Singer and Creutzfeldt, 1970).

SYNAPTIC ORGANIZATION IN THE VISUAL SYSTEM 641

FIGURE 11 Simulation of the response of an on-center cell of the LGB to light spots shone into different parts of its receptive field. A. Original averaged responses recorded with a quasi-intracellular electrode. The stimulus positions I-V (top to bottom) correspond to the sketch in C. The responses are averaged from 10 identical stimuli. B. Simulated responses based on the model shown in

Figure 10 and drawn schematically in C. The excitatory input is the activity of one retinal on-center ganglion cell. The inhibitory input is the weighted sum of four geniculate off-center cells (broken lines in C). Same time scale in A and B. (From Singer and Creutzfeldt, 1970).

influences when light is not shone into the RFC. Furthermore, an improvement in the discrimination of successive brightness contrasts could result from the diminution of inhibition simultaneously with the increase of excitatory input (disinhibition). No significant improvement of spatialcontrast discrimination, however, is brought about by the proposed mechanism.

Cortical synaptic organization

In the visual cortex we find yet another principle of synaptic organization. Again one must distinguish between the primary afferents (geniculocortical pathway or optic radiation) and those from such other origins as other cortical areas, other visual structures, and nuclei not primarily concerned with vision ("nonspecific" systems). Only the primary specific input is considered here.

Cortical EPSPs are much smaller than geniculate relay cell EPSPs, which are about half of the threshold. The ongoing synaptic bombardment, present without stimulation, keeps the membrane potential fluctuating between 5 and 10 mV below threshold and only rarely reaches the latter

(Creutzfeldt and Ito, 1968). For this reason, the "spontaneous" rate of most cortical cells is low. If an excitatory afferent fiber is activated by light, the temporal summation to reach threshold takes 30-60 milliseconds, even if the fiber discharges as fast as 150 to 200 times per second. Thus, the response latency to a light stimulus does not say much about the number of synapses lying between the afferent fiber and the cortical cell. Because various afferents with different functional properties converge on single cortical cells, stimuli in different parts of the receptive field may result in excitation, inhibition, or disinhibition. The time course of this disinhibition is even slower than that of direct excitation. The question of linear or nonlinear transmission of cortical cells is of little significance in the context of the organization of their synaptic input. A linear relation between membrane potential and discharge frequency is also of minor importance for transfer properties of cortical nerve cells, because nonlinear interaction of EPSPs and IPSPs must be expected on the dendrites in a manner that so far has defied a simple experimental or theoretical approach (Creutzfeldt et al., 1969).

The many receptive-field shapes of neurons in the pri-

mary visual cortex (Hubel and Wiesel, 1962, 1968) are caused by the numerous combinations of afferent fibers impinging upon them. Intracellular recordings show that excitation or inhibition of cortical neurons may originate from geniculate on-center or off-center fibers (Creutzfeldt and Ito, 1968). The question of whether the inputs are monosynaptic or polysynaptic remains open. The input combinations of excitatory and inhibitory on-center and off-center fibers varies from cell to cell, but nearby cells often have a similar or an identical input.

Figures 12 and 13 show examples of the intracellular analysis of the receptive fields of two cortical cells. In the cell in Figure 12, the central excitatory field (stimuli 3, 4, 8, 14) is flanked by two inhibitory fields (stimuli 1, 2, 6, and 10, 11). The excitatory field is caused by the excitatory input from an on-center fiber, the inhibitory fields by the inhibitory inputs from two on-center fibers with different receptive-field centers. The responses of this cell could be simulated in a computer model (Figure 12D) when only these three input fibers with the field centers a, b, and c, as shown in the stimulus map, are assumed. This cell would respond maximally to a horizontal bar of light that does not touch the inhibitory flanks.

Figure 13 shows the more complicated field of a neuron that was directionally sensitive to movement. The excitatory responses were maximal to stimuli 12, 13, 6, and 7. Inhibitory-on responses were elicited from areas 10 and 11, and a less powerful excitatory-on response, interrupted by a strong inhibition, from area 9. The functional behavior of this neuron, in spite of its complexity, could be simulated when the convergence of two excitatory on-center fibers with centers between stimulus 12 and 13, an inhibitory oncenter fiber with a center between 10 and 11, and an excitatory off-center fiber with its center in the lower left quadrant of the stimulus map are assumed. This neuron responded best to a stimulus moving from right to left (Figure 14, page 646). When the stimulus was moved from left to right, inhibitory potentials (arrow in C) from the inhibitory-on area near 11 interrupted the excitation brought about by the excitatory field between 12 and 13. In many cells, however, the directional movement sensitivity was the result of excitatory connections with off-center fibers; the sensitivity was maximal when a dark stimulus entered the field and when a light stimulus left the field of this offcenter input.

The most interesting conclusion of our intracellular analysis was that the responses of most simple visual cortex cells (Hubel and Wiesel, 1962) could be explained by the convergence of only a few afferent fibers with relatively simple response patterns, i.e., probably of direct geniculate origin. Often the resulting fields were such that lines of light in a certain direction were maximally effective (as most neurons in the studies of Hubel and Wiesel, 1962 and

1968). The exact anatomical basis of such an organization is still uncertain, as we cannot say from which cell type (pyramidal or Golgi cells) the records were taken. In any case, it indicates that a few afferent fibers provide the major synaptic input and, thus, the basis for the functional behavior of cortical cells. On the other hand, the similarity of certain aspects of some central receptive fields with regard to stimulation of both eyes (especially the responses to moving stimuli, as shown by Bishop, this volume) suggests that the selection of a limited number of afferents may not be the only determinant of the functional organization of cortical cells, because it would then be necessary to make the improbable assumption that the same types of afferents from both eyes are selected by the same cells. The "modular shape" of the dendritic tree of these neurons may also play a role. Further experimental data are necessary before such questions can be clarified.

Intracellular analysis of visual cortex cells has led us to the following conclusions (Creutzfeldt and Ito, 1968; Creutzfeldt, 1968b): The combination of inputs to a cell explains the existence of certain "optimal" stimulus shapes. The number of stimuli influencing each cortical cell and the variability of receptive fields in different cells make unlikely the hypothesis of an organization in which one particular cell "recognizes" a specific pattern, i.e., acts as a line, movement, or directionality detector, and conveys this information to the next group of neurons. It is true that, at first glance, this organization suggests a decoding mechanism with separate, well-defined functions for different cell groups. However, the within-cell and between-cell variety of functional combinations is difficult to force into such a scheme, and if the living cortex actually operated in this manner the available information "seen" by the eye would be reduced considerably. In fact, computers with patternrecognition programs based on such concepts "recognize" very little. In short, we are unable to interpret the functional organization of the visual cortex in terms of behaviorally relevant information analysis. We know only that the cortex is necessary for visual-pattern analysis, but we lack sufficient knowledge about the behaviorally important signals extracted and transmitted by the visual system and about what actually "reaches" the animal.

Summary

This paper discusses some principles of synaptic organization in the retina, the lateral geniculate body (LGB), and the visual cortex and their implications for the transfer properties of the various parts of the visual system.

The supported view is that the receptive-field center of a retinal on-center ganglion cell is determined by the distribution of its dendrites. The sensitivity distribution within the receptive-field center corresponds to the distribution of

histograms of some stimuli. D. Computer simulation of the cell responses, based on the assumption that the excitatory input comes from one geniculate on-center fiber situated in A on the B diagram, and the inhibitory input from two geniculate on-center fibers situated in B and C. (After Creutzfeldt and Ito, 1968.)

FIGURE 13 Responses of a cortical cell (area 17) to spots and bars of light shone into different parts of the receptive field. The cell is movement-sensitive with directional preference (see Figure 14). A. Averaged slow-potential responses (sum

of IPSPs and EPSPs) to 10 stimuli. The numbers on the responses correspond to the stimulus numbers in the map (C). B. PST histograms of some stimuli. (From Creutzfeldt and Ito, 1968.)

FIGURE 14 Movement response of the cell shown in Figure 13. In A (slow recording speed) and C (fast record), the stimulus moves from left to right (the numbers below the record correspond to the stimulus positions in the stimulus map of Figure 13). In B (slow record) and D (fast record) the stimulus moves from right to left. The response is

stronger for these movements than during movement in the other direction (A and C), because IPSPs (arrow in C) interrupt the excitatory response. Note different time scale in A and B from that in C and D. (From Creutzfeldt and Ito, 1968.)

dendritic density. It is suggested that synaptic contacts between bipolar and ganglion cells are made by chance, i.e., whenever a bipolar-cell "axon" meets a ganglion-cell dendrite. A morphological model based on this assumption is suggested, and simulation of responses to light stimuli are demonstrated and compared with experimental data. Excitation is not summated linearly within the receptive-field center. Possible mechanisms for this are discussed, and experiments are described. Nonlinear signal summation takes place in the receptor-bipolar complex and, because of electrotonic spread and interaction of excitatory processes along the dendrites, at the ganglion-cell input level. At higher excitation levels, the maximal firing rate of retinal ganglion cells limits their response. The result of these different nonlinearities is that individual ganglion cells give incomplete information on stimulus brightness and spatial extent. Gain control, caused by neuronal adaptation at the receptor site, is another mechanism of nonlinear retinal transmission.

In the lateral geniculate body (LGB), the synaptic organization is such that the branches of optic-tract fibers have essentially one-to-one excitatory contacts with the relay cells. Each LGB relay cell thus receives a direct excitatory input from only one optic-tract fiber. Cells in the LGB that have an on-center fiber input are inhibited by off-center cells; off-center cells are inhibited by on-center cells. The receptive fields of these mutually inhibitory on-center and off-center cells are near each other. This arrangement does not improve the spatial dissolving power of the visual system. Only the sensitivity to successive contrasts in brightness may be slightly improved because of simultaneous excitation of the excitatory input and inhibition of the inhibitory input (disinhibition), or vice versa. The main function of the LGB may therefore be seen in the combination of the retinal and nonretinal inputs into the same relay cells. The information-transmission properties of a monosynaptic one-to-one relay are discussed, and it is shown how a nonlinear transfer is brought about by summation of irregularly timed EPSPs.

Visual-cortex cells receive a variety of inputs. In area 17, the main retinogeniculate input into one cortical cell consists of two to five radiation fibers. They may be excitatory or inhibitory and may come from geniculate on-center or off-center cells. These receptive-field centers overlap and have center distances of up to 2–3 degrees. Optimal stimuli are those that simultaneously inhibit inhibitory and activate excitatory input fibers. Such optimal stimuli are often bars of light or darkness. Moving stimuli are usually more efficient than stationary stimuli, because of the successive activation of several excitatory inputs. Direction-specific movement responses result from the successive invasion of the receptive fields by excitatory off-center and on-center input fibers or of excitatory and inhibitory on-center input fibers. Many possible input combinations were found. Cortical neurons are part of a pattern-recognition mechanism, but whether the observed optimal stimulus shapes are significant elements of its algorithm is questioned.

57 Functional Association of Neurons: Detection and Interpretation

GEORGE L. GERSTEIN

DURING THE PAST 15 YEARS, the functions of many portions of the nervous system have been examined through the study of single neurons, each individually observed for some period of time. In sensory systems, in spite of the prevalence of spontaneous neural firing, it has been possible to determine the probabilistic relations between the presentation of an appropriate stimulus and the resulting change in firing pattern. Both in terms of stimulus detection and in terms of stimulus coding, it is apparent that the firing pattern of a single neuron does not carry enough information to account for the behavioral capabilities of an entire organism. To detect a change in firing pattern caused by a stimulus, for example, it is often necessary to sum the responses to repeated stimulus presentations, even though the stimulus intensity is far above the psychophysical detection level. Even if the response pattern of a single neuron is well defined, most measurable characteristics of the response pattern (such as latency, amplitude, shape of envelope, and so forth) turn out to be multivalued functions of various stimulus parameters. The characteristics of the firing pattern can therefore not be used uniquely to decide what the stimulus parameters were. Fortunately, the multivalued functions relating response pattern and stimulus parameter differ from neuron to neuron, so that the ambiguity can be resolved by combining information from several neurons. The ability of an organism to detect and determine stimulus parameters in a single presentation overwhelmingly suggests that such ensembles of neurons must be involved in the processing of sensory information. It would seem probable that most complex integrative functions in the nervous system also involve simultaneous activity in groups of neurons. Such functional groupings may well have boundaries and internal relationships that change in time or with the nature of the task.

The number of neurons comprising a functional asssembly might be in the hundreds for mammalian nervous systems; smaller groupings are likely in simpler nervous systems. Although the technology for examining such large groupings does not yet exist, methods have become available for the recording and interpretation of the simultaneous activity of small numbers of neurons. Two general types of experiment can yield such information. With intracellular recording, a group of functionally related neurons is available for study, if it be assumed that individual postsynaptic potentials are indentifiable. Little is known, however, under these conditions about the relative spatial arrangement of such neurons. In contrast, with extracellular recording, a group of neurons that lie within a small volume may be studied, but little is known *a priori* about their interconnections. The two types of experiment record, respectively, a functional group or a spatial group of neurons. The purpose of the present paper is to illustrate the detection and interpretation of neuronal interactions within such a group.

Recording methodology

The simultaneous recording of electrical activity from several neurons can be accomplished by a variety of methods. In order to study neuronal interactions by the analytic methods reviewed in this paper, it is necessary to sort such compound data so that the activity of each observed neuron as a function of time is known individually. Various solutions for this problem have appeared in the literature; choice among the alternatives depends on the circumstances of the experiment and the detailed nature of the data.

INTRACELLULAR RECORDINGS The action potential of the impaled neuron is easily separated from all other electrical activity by an amplitude discriminator. Postsynaptic potentials (PSPs) from synaptic connections incident on the impaled neuron can be resolved individually only if they arrive at a rate sufficiently low so that they overlap rarely in time, a condition that is more often realized in invertebrate recordings. PSPs from synapses at different locations on the impaled neuron should have different amplitudes and shapes because of the electrical properties of the dendritic membrane (Rall, 1967). These PSP shape differences can be used by a computer program to identify similar shapes in the recording, and thus to mark trains of particular synaptic events. An elegant program for this purpose was described

GEORGE L. GERSTEIN Departments of Physiology and Biophysics, University of Pennsylvania, Philadelphia, Pennsylvania

by Hiltz (1965); the program will sort PSP shape even if there is partial overlap or a rapidly changing baseline potential. A much simpler program using a library of PSP shapes that are chosen by the operator has been described by W. Simon (personal communication).

EXTRACELLULAR RECORDINGS If multiple electrodes are used, each of which isolates a single action potential, the experimental objectives are immediately realized. With multiple microelectrodes, however, there is difficulty in controlling the relative positions of the tips, and there is an unknown amount of damage to the tissue. A number of workers have chosen to use single microelectrodes with enough tip area exposed to allow the recording of several different neurons. The relative geometry of electrode tip and each neuron is different, so that, in general, each neuron produces a different action-potential shape and amplitude in the composite recording. Individual spike trains can then be determined by sorting the data according to action-potential shape. Methods for doing this have been devised with computer programs (Gerstein and Clark, 1964; Simon, 1965; Keehn, 1966) and with hardware devices (Glaser and Marks, 1968). Each of these methods of sorting of spike shape is subject to error; a careful evaluation of the reliability and sources of error for these methods can be found in the review by Glaser (1970).

An illustration of spike shape-sorting methods taken from our own work (Gerstein and Clark, 1964) is shown in Figure 1. Short sections of the raw data are shown at the top of the Figure, and include action potentials of several different amplitudes. More careful examination with the oscilloscope, as in the time-exposure at the top right of the Figure, shows that several different action-potential shapes can indeed be identified. Several stages of the sorting process are illustrated by the histograms in the lower part of the Figure. A "standard" waveform, labeled "0," is chosen arbitrarily from the data, and all other spike shapes in the data are compared with it. The comparison is made by a mean-square difference across the 32 data points that comprise each action potential. The weighting of different points in this calculation can be adjusted at will. The histogram labeled "Stage 0" shows the distribution of the population of spikes according to increasing dissimilarity of shape from the standard waveform. The population falls into a multimodal distribution; the farthest left peak can be defined as the portion of the population of action-potential shapes that is most similar to the standard waveform. This portion of the population is identified as shape class 0 and is removed from further consideration. A new standard waveform is chosen from the residue, and the process iterated in order to identify shape class 1. The process is sensitive: shape class 1 and shape class 2 action potentials have similar amplitudes and differ mainly by the shape of the afterpotential. The long tail of the distribution in the Stage 3 histogram represents the various waveform overlap events. Such superpositions cannot be handled by this technique, and represent an unavoidable gap in the data.

The mean-square method of shape comparison used here can be explained in terms of a geometric model. Consider a 32-dimensional property space; the 32 voltage values that determine a given action potential define a single point in this space. We seek to determine whether there are clusters of points that correspond to populations of action potentials that are discrete in shape. The choice of a standard waveform corresponds to the choice of a single point in the property space. We then calculate the distance to all other data points in the space, and plot these distances as a histogram. If the original choice of origin for the distance measurement fell within a well-defined cluster, the histogram would be multimodal. Only the histogram peak corresponding to the smallest distance is well defined; two or more point clusters far from the chosen origin might occur at the same distance, and hence would be indistinguishable in the histogram. Other methods of shape comparison can also usefully be viewed in terms of a multidimensional property space.

Analytic methodology

In the following discussions we assume that the basic data have been sorted into separate spike (or PSP) trains. We assume that (identical) stimuli occurred at instants S_i , while action potentials from spike train A occurred at instants A_i , and action potentials from spike train B occurred at instants B_k .

We may apply all the usual single-unit measures to such data in order to make a statistical description of each spike train (interval histograms, autocorrelograms, and so forth). It is also possible to examine the relationship between each firing pattern and the stimulus by computing the peri-stimulus-time histogram (PST histogram). A more detailed discussion of the mathematical meaning of the various computations that are appropriate for the characterization of a single train of action potentials can be found in Perkel et al. (1967a). In the present context of multiple, simultaneously recorded spike trains, these measures may be used to assess the similarity of response properties within the group of neurons that is being sampled. If data are gathered with a single extracellular electrode, all the observed neurons lie within a small volume, which might be several hundred microns in diameter. We may examine whether there is a relationship between such spatial contiguity and the response pattern to an appropriate stimulus. An example of such a measurement is shown in Figure 2. This small volume of cochlear nucleus contained a heterogeneous population of active neurons, although other, similar experiments have shown more homogeneous response properties.

FIGURE 1 Sorting of spike shapes in a multiple neuron recording. Raw data at top; inset (top right) shows several distinct spike shapes in time exposure on a triggered oscilloscope. Four stages of the sorting process are below. In each histogram, below, all spike waveforms in the data are compared with the "standard" waveforms shown. In each case, the peak at the left represents spike waveforms that are most

similar to the standard waveform. The identified waveforms are removed from the data at each stage of the separation process, so that each successive stage is performed on a smaller population of waveforms and waveform classes. Dissimilarity number represents the difference in waveform.

FIGURE 2 PST histograms from three simultaneously recorded neurons in cochlear nucleus of an anesthetized cat. A special tungsten electrode was used, and neurons were probably within a 200-micron sphere. Tone-burst stimulus is indicated at the top. PST histograms are shown with high

time resolution in the right column to show the detailed firing patterns during stimulus presentation. Neuron shown at top was excited by stimulus, neuron in middle was inhibited, and neuron at bottom was unaffected.

When data recorded simultaneously from several neurons are available, it is interesting to make various interspike-train measurements. These allow the detection and assessment of direct interaction between the neurons. In addition, it is possible to evaluate the effect of the stimulus on such interactions and to estimate the degree of common input from sources other than the stimulus. These measurements can be used to derive a "logical wiring diagram" for the neurons under observation. Furthermore, together with the appropriate experimental design, they can be used to search for parallel-line coding in the transfer of sensory information. A detailed discussion of computations appropriate for the characterization of simultaneously recorded spike trains can be found in Perkel et al. (1967b). More recent developments are in Gerstein and Perkel (1969).

Several different interspike-train measurements have proved appropriate for various types of problems, as described below. For each of these measurements, it is important to have available a control calculation that predicts the appearance of the measurement if the two (or more) spike trains are completely unrelated. Such control calculations are made necessary by the statistical variability of the spike trains and by the need to sort out effects of stimulation from effects of direct interaction between, or of common input to, the observed neurons. The three measurements described here are variously related to cross correlation of two (or more) spike trains.

CROSS-INTERVAL HISTOGRAM Time intervals are measured from a given spike of train A to the nearest preceding and succeeding spikes of train B. This is repeated, using each spike of train A as origin, and a histogram is compiled. It should be noted that, unlike the ordinary cross correlation, this cross-interval histogram is in no way related to the histogram that would be obtained if the roles of the two spike trains in the measurement were interchanged. In general, it is necessary to compute the cross-interval histogram with both the A and the B spike trains as origins. A satisfactory control for this measurement is known from renewal theory (Cox, 1962) and is calculated from the interval histograms of the two spike trains. The cross-interval histogram is particularly useful for the detection of relationships that have a short time course of the same general duration as the mean interspike interval of the two spike trains. Relationships with a longer duration are lost in this measurement, because they may involve a time considerably longer than that to the next spike.

CROSS-CORRELATION HISTOGRAM From a given spike of train A, the time intervals are measured to all preceding and succeding spikes of train B that fall within a selected time duration. This is repeated, using each spike of train A as origin, and a histogram is compiled. Unlike the cross-interval histogram, interchange of the roles of the two spike trains simply produces the same cross-correlation histogram with a reversal of the time scale. If the two spike trains are completely uncorrelated, and if their statistical properties are constant in time, the cross-correlation histogram will be flat (to within statistical uncertainty). If, however, data were taken during appropriate stimulation, both spike trains could show rate variations that are related to the stimulus, and a more complex procedure would be needed to obtain a control measurement. One possible control is obtained by convolution of the PST histograms from each spike train. A more readily calculated control measurement is applicable if the stimuli are periodic. Either spike train A or spike train B is segmented at the stimulation instants, and these segments are shuffled. A cross-correlation histogram is then constructed between the intact spike train and the shuffled spike train. The effect of this shuffling procedure is to destroy detailed correlation between the two spike trains while all effects caused by the periodic stimulation are left intact. The cross-correlation histogram and its controls are particularly useful for the detection of relationships that have a time course much longer than typical interspike intervals, but shorter than typical interstimulus intervals. Such relationships will appear in the cross-correlation histogram as deflections from the shape of the control histogram.

JOINT PERI-STIMULUS-TIME SCATTER DIAGRAM This consists of a scatter diagram of the joint occurrences of spikes in trains A and B relative to the times of stimulation. The ordinate of each point plotted corresponds to the time between a stimulus event and a spike in train A (for example, A_j -S_i), and the abscissa corresponds to the time between the same stimulus event and a spike in train B (for example, B_k -S_i). For each stimulus event, a point is plotted for each combination of S-A and S-B time intervals, both of which fall into a specified range. A spike in train A will give rise, in the scatter diagram, to the same number of points as there are spikes in train B within the specified time range about the stimulus (and vice versa). This scatter diagram is a generalization of the PST histograms for the two spike trains and of the cross-correlation histogram, and contains information beyond that available in those histograms. The diagram is particularly useful in sorting out the portions of relationships between spike trains that result from direct interaction between the neurons and those that result from common, or stimulus-related, input to the two neurons. Point densities in the scatter diagram are differently affected by each of these relationships: (1) direct stimulus effects on each neuron are expressed as bands of altered point density that are parallel to the coordinate axes; (2) direct interactions between the neurons are expressed as bands of altered point density that are parallel to the principal diagonal; (3) stimulus-related changes in the direct interactions are expressed as changes in the band structure along the direction of the principal diagonal; and (4) common input to the two neurons other than from the stimulus is also expressed as diagonal band structure, but is frequently more diffuse than the diagonal bands produced by direct interactions between the neurons.

In effect, the joint PST scatter diagram permits examination of the time structure of correlation between two spike trains. It should be noted that the scatter diagram is easily extended to three (or more) simultaneously recorded spike trains (Figures 10 and 11). Thus it allows detection and measurement of functional grouping of more than two neurons at a time.

An appropriate control measurement can be obtained for the scatter diagram by the same technique that has been described for the cross-correlation histogram. One spike train is segmented at the stimulus events and shuffled. The scatter diagram is again constructed between the intact spike train and the shuffled spike train. The principal effect of this procedure is to destroy all detailed correlation between the two spike trains, and consequently to eliminate all diagonal structure from the scatter diagram, although directly stimulus-related structure and the general "background" point densities are preserved.

Categories of functional interaction

The several measures described above can be used individually or in combinations to study multiple, simultaneously recorded spike trains. The initial objective of such study for extracellularly recorded spike trains is to define an equivalent "wiring diagram" for the connections that may exist between the observed neurons. This step, of course, is not always needed if the data originated from intracellular recording with PSP identification, because the functional relationships between the presynaptic and postsynaptic neurons are already defined. If, however, relationships between different identifiable PSPs are to be examined, the problem is logically equivalent to the case of multiple extracellular recording.

In subsequent portions of this paper, I discuss connections

between the observed neurons and connections from inferred (but not observed) neurons in terms of the stylized diagram shown in Figure 3. The two directly observed neurons are labeled A and B; known stimulus sources are represented by S. Inferred interneurons are labeled I, and inferred sources of common input are represented by D. Arrows show the connections between the various elements and represent either excitatory or inhibitory effects. Several of the pathways are redundant, even in this simple diagram. For example, the functions of the explicit pathways drawn from S to A, S to B, D to A, D to B, and S to D could be accomplished within the interneuron box I. The logical functions indicated in Figure 3 could also, of course, be accomplished by a hierarchy of more complex circuits, because chains of additional interneurons could be interposed between any two elements without altering function. Unfortunately, the sensitivity of our analytic methods is not sufficient to allow choice between such alternatives, so that the description of the observed interrelationships can be left in the simplest possible terms. It should be noted that in most data there is evidence for only a few of the possible interconnections shown in Figure 3.

Once the connections of the observed neurons have been established in the rather oversimplified terms of Figure 3, the stimulus conditions of the experiment may be varied. Such strategy allows detection of changes in the neural connections as a function of the stimulus conditions, and simultaneously allows detection of possible parallel-line coding schemes.

NEURONAL INTERACTION NOT AFFECTED BY THE STIMULUS Cross-interval histograms for two neurons in cochlear nucleus of an anesthetized cat during spontaneous and stimulated conditions are shown in Figures 4 and 5. The histograms in Figure 4 were taken with spikes from neuron 22–0 used as origin; in Figure 5 the roles of the two spike trains were interchanged, and spikes from neuron 22–1 were used as origin. Superimposed on each histogram is the appropriate control calculation corresponding to the assumption that there was no correlation between spike trains.

The general shape of these cross-interval histograms is different, depending on whether the stimulus was presented and on which of the two spike trains was used as origin. Despite the statistical variability of the histograms, there is clear agreement between the over-all histogram shapes and the control calculation. (The control curve is much smoother than the histograms in each case, because it is calculated from a probability distribution function; the cross-interval histograms themselves are estimators of probability densities.) Near the origin of each histogram, however, is a single peak that deviates from the control calculation by an amount that is large in comparison to the typical statistical variability. These peaks are at -3 milliseconds in the histograms of

FIGURE 3 A schematic diagram useful for considering pathways to and between the two observed neurons, A and B. S represents stimulus sources; I represents interneurons; D represents other common inputs. Connections can be excitatory or inhibitory.

Figure 4 and at +3 milliseconds in the histograms of Figure 5. An interpretation that is consistent with all four histograms is that neuron 22-1 has a far greater-than-chance probability of firing 3 milliseconds before neuron 22-0, independent of the stimulus conditions; conversely, neuron 22-0 has a far greater-than-chance probability of firing 3 milliseconds after neuron 22-1. Both neurons fire frequently at other relative time intervals, although such cross intervals have a chance distribution. In physiological terms, the preferred relative time interval may represent either a direct synaptic connection between the two observed neurons with a conduction time of 3 milliseconds, or it may represent a common input to the two observed neurons. If the latter is true, there is a 3-millisecond difference in the conduction time between the common source and the two observed neurons. Both pathways are indicated in Figure 3. Choice between the alternatives is difficult without additional information. Experience with other data and with computer stimulation, however, suggests that very narrow peaks, as in the cross-interval histograms of Figures 4 and 5, are caused by direct connection between the two observed neurons. Histogram peaks that are the result of common input to the two observed neurons tend to be considerably wider than those shown in Figures 4 and 5.

NEURONAL INTERACTION AFFECTED BY THE STIMULUS Cross-interval histograms for two neurons in visual cortex of an unanesthetized, chronically prepared cat are shown in Figure 6, page 656. Neither of these units showed much spontaneous activity, but both responded actively to a moving parallel-bar pattern.

FIGURE 4 Cross-interval histograms of firings from two neurons in cochlear nucleus of an anesthetized cat. The left histogram was taken during spontaneous conditions; the right histogram was taken during stimulation by tone bursts of 800 msec, presented at 1 per second, containing a

frequency that was within the auditory response area of both neurons. Control calculation for the case of no interaction between the observed neurons is indicated by the dotted curve.

There is excellent agreement between the control calculation and the left cross-interval histogram that corresponds to vertical motion of the bar pattern. The missing bars of the histogram near the origin are an artifact resulting from the inability of the spike shape-sorting system used here to deal with superposition of action-potential waveforms when the two neurons fire almost synchronously. This means that, during vertical motion of the bar pattern, the two spike trains showed only chance time relationships. In the second histogram of Figure 6, which corresponds to diagonal motion of the bar pattern, agreement between the control calculation and the cross-interval histogram is good only to the right of the origin. To the left of the origin, the histogram shows a series of peaks situated at approximately 3, 11, and, possibly, 22 milliseconds. This means that neuron 50-2 tends to follow the firings of neuron 50-3 by these preferred intervals, although no reciprocal relationship is evident. This time structure is unlikely to be related directly to the passage of the stimulus bars over the receptive fields, because such passage occurred only every 600 milliseconds. In physiological terms, the preferred relative time intervals may represent direct synaptic connection between the two observed

neurons via interneuronal chains of three different lengths. Alternatively, the preferred time intervals may represent a common source of input to the two observed neurons through similar interneuronal chains. Choice between these alternative explanations cannot be made uniquely, although the narrow peaks would favor direct connection as the more likely situation. In either case, it should be noted that the occurrence of a preferred timing relationship between the two spike trains depended on presentation of a "favored" stimulus. In terms of Figure 3, these data imply a pathway S to I that is able to modulate the pathway A to I to B.

The data shown in Figure 6 represent a situation in which the two stimulus conditions could not be differentiated clearly by examining the peri-stimulus-time (PST) histograms of the two observed neurons. The individual spike trains showed little difference during the two stimulus conditions. The correlation structure between the two spike trains did, however, show a dependence on the stimulus condition. Potentially, such a correlation structure between spike trains could, if it is stimulus selective, be used as a coding mechanism. Whether such codes are actually used in the nervous system must be determined in each case by identify-

Unit 22-0 from unit 22-1

FIGURE 5 Cross-interval histograms of the same data as in Figure 4, but with the roles of the two spike trains interchanged. Control calculation as in Figure 4.

ing an appropriate decoding mechanism at the neural level upon which the correlated neurons project.

COMMON INPUT CAUSED BY STIMULUS Figure 7 shows cross-correlation histograms under different stimulus conditions for the same two neurons in cochlear nucleus as are seen in Figures 4 and 5. These cross-correlation histograms were calculated by using the spike train of unit 22–0 as origin; it is not necessary to make the reciprocal calculation. The time scale was chosen to encompass the time between stimuli. The short-duration interaction effects discussed with the aid of cross-interval histograms in Figures 4 and 5 are barely resolved by the long time scale in Figure 7.

The cross-correlation histogram corresponding to the spontaneous condition is flat to within the statistical variability. This suggests that, during such spontaneous conditions, there is no correlation between the two spike trains. Both cross-correlation histograms in the stimulated conditions show, however, considerable deviations from flatness. These deviations appear to be periodic, with the same period as the stimulus presentations, and signify that the two spike trains are correlated in a time-varying way that is related to the stimulus. It is now necessary to determine whether such correlation structure is the result of direct interaction be-

tween the two observed neurons, or whether it simply represents the simultaneous changes in firing probability that are produced in each neuron by the presentation of the stimulus. Such determination is most easily achieved by comparing the cross-correlation histograms with the appropriate control calculations. Such controls correspond to spike trains with the identical time structure with respect to the stimulus, but with no direct correlation (see section on Analytic Methodology). The desired comparison for the middle cross-correlation histogram in Figure 7 is shown in Figure 8. The black dots represent the control calculation and are superimposed on a gray histogram, which replicates the one in Figure 7. Unlike the control calculation used for cross-interval histograms, the present calculation does not show a reduced statistical variability. Nevertheless, it seems clear that there is good agreement between the two measurements shown in Figure 8. We conclude that the correlation structure that is implied by the histograms of Figure 7 is entirely the result of stimulus-related firing by the two observed neurons, and that no direct interactions or connections between them need be invoked (except for those discussed in conjunction with Figures 4 and 5). In terms of the diagram of Figure 3, these data imply only pathways from S to A and from S to B.

FIGURE 6 Cross-interval histograms of firings from two neurons in visual cortex of a chronically prepared cat. Each stimulus bar subtended 2° from the cat's eye and the entire pattern was moved sinusoidally through 20° once

every 6 seconds. The direction of movement is indicated below each histogram. As on Figures 4 and 5, the control calculation is indicated by the dotted curve.

COMMON INPUT ALTERED BY STIMULUS Cross-correlation histograms for two neurons in cochlear nucleus of an anesthetized cat are shown in Figure 9. The left histogram shows the cross correlation during the spontaneous condition. The two histograms on the right represent the cross correlation and its control calculation for data obtained during acoustic stimulation by 50-millisecond tone bursts of an appropriate frequency.

The cross-correlation histogram corresponding to the spontaneous condition shows a small, broad peak placed symmetrically around the origin. This means that the observed neurons tend to fire within approximately 100 milliseconds or less of each other, although on the average neither neuron leads the other. The most likely physiological explanation of the histogram is that these neurons have a common source of synaptic input. Other inputs to each neuron exist also, including input from stimulus sources (as discussed under Common Input Caused by Stimulus and below). These other inputs would insure that neither neuron tends to lead in response to input from the common source.

When the cross correlation and control calculation corresponding to the stimulated condition are compared, there appears to be a good fit in regions to the left of the origin and in regions to the right of ± 0.2 second. In the first 0.2 second to the right of the origin the correlation histogram is somewhat higher than the control calculation. The correlation in excess of that attributable to stimulus effects (as determined by the control calculation) is therefore not symmetrically arranged with respect to the origin. In this case, presentation of an appropriate stimulus has changed a cross

FIGURE 7 Cross-correlation histograms for two neurons in cochlear nucleus of an anesthetized cat. FIGURE 8 Control calculation for the middle cross-correlation histogram shown in Figure 7. The dots are the control; the original histogram is shown in gray bars. correlation that is symmetrical around the origin into one that is asymmetrical around the origin. In physiological terms this suggests that the nature of the common input to the observed neurons has been altered in a nonspecific way by the presentation of the stimulus. In terms of Figure 3, these data suggest pathways directly from S to A and S to B, pathways from D to A and D to B, and finally from S to D. The last pathway presumably has tonic effects on D, the common source.

TEMPORAL STRUCTURE OF NEURONAL INTERACTION The methods we have examined above for determining the correlation between two spike trains all treat the entire available stretch of data uniformly. It may be desirable to know whether the correlation structure itself is time varying, particularly with respect to the instants of stimulus presentation. It also may be desirable to extend the analysis to three or more simultaneously recorded spike trains. Both objectives are met by plotting joint PST scatter diagrams; these are shown in Figure 10 for three neurons from the pleural ganglion of *Aplysia*, and in Figure 11 for three neurons from auditory cortex of a chronically prepared cat. Both Figures are presented as stereo pairs and are best viewed if merged. The origin for each cube is at the center rear, and the rear edges are the coordinate axes along which are

plotted, respectively the S to A, S to B, and S to C time intervals, in which A, B, and C are the three spike trains. The two rear faces and the bottom of each cube are planes which contain the two-dimensional, joint PST-scatter diagrams for the neuron pairs A–C, B–C, and A–B, respectively.

Various clusters of points are visible in both Figures, although with greater clarity in Figure 10, because the longtime scale reduces the apparent variability of firing. Each such cluster is readily identifiable in terms of particular aspects of each spike train or in terms of correlation between them. The lines of high density near and parallel to each of the coordinate axes represent the direct, stimulus-related firing of each of the three neurons. Some caution is needed in assigning these regions of altered density, because there is multiple representation. The line of high density in the A–B plane near the B axis represents the stimulus-related increase of firing in neuron A; conversely, the two lines of high density in the A–B plane near the A axis represent the stimulus-related increase of firing in neuron B.

Clearly visible in each coordinate plane are diagonal lines of high density. These represent highly correlated firing of the neurons in pairs. It should be noted that the point density along any of these diagonals is not uniform. There is a region of higher point density near the origin. This means that each pair of neurons has a high probability of firing

FIGURE 10 Joint PST scatter diagram for spike trains from three simultaneously recorded neurons in pleural ganglion of *Aplysia*. Stimulus was an electric shock to one of the nerves (W. Kristan, personal communication). Origin is at the center rear corner of the cube, and represents the instant of stimulus delivery. Activity of each neuron is plotted, respectively, along axes labeled A, B, C. Each edge of the cube is 10 sec long. This and Figure 11 are arranged for stereoscopic viewing. The left image is intended for the left eye. Thus, the eyes should be converged as if looking at a distant object, although focused on the page.

FIGURE 11 Joint PST scatter diagram for spike trains from three simultaneously recorded neurons in auditory cortex of a chronically prepared cat. Stimuli were 50-msec tone bursts of "best" frequency, 2 per second. Each edge of the cube is 0.5 second long.

with a particular small relative time interval; this probability is itself related to the instants of time that stimuli are presented.

In addition to the diagonal lines of high density in the coordinate planes, a line of high but varying density extends along the major diagonal of the cube in Figure 10. This represents the near-coincident firing of all three neurons. An interpretation consistent with the above observations is that all three neurons represented in Figure 10 had input from the stimulus and from some other common source. The latter input was itself modulated by the stimulus. The identification of the diagonal densities in Figure 10 as resulting from common input rather than direct connections (for example, from A to B to C) was possible, because all three neurons were recorded intracellularly and showed coincident PSP input.

The analysis of three cat neurons shown in Figure 11 has more apparent variability because of the shorter time scale. Nevertheless, most of the same features are visible; bands of higher density fall along the coordinate axes, on the diagonal of each coordinate plane, and along the principal diagonal of the cube. The interpretation can be that all three neurons had input from the stimulus and from some other common source, which was itself modulated by the stimulus. The choice between the possibility of direct connection and common source for these data is based on the width of the diagonal structures in Figure 11. Far narrower diagonal structure is found in some cases (Gerstein and Perkel, 1969) and is more likely to be the sign of direct interconnection between the observed neurons.

Conclusion

As shown in the examples above, various inferences may be drawn from the analysis of multiple, simultaneously recorded, spike trains. The initial result is establishment of an equivalent "wiring diagram" for the connections that may exist to and between the observed neurons. When the appropriate control calculation is made, the effects of stimulus on the observed neurons can be assessed. Residual correlation suggests the presence of direct interaction between, or common input to, the observed neurons.

If interactions between the observed neurons exist, they may vary in time or in a manner related to the presentation of the stimulus. By appropriate experimental design, it is possible to seek the existence of stimulus coding in such form. If it is stimulus selective, correlation in the firings of two or more neurons may itself serve as a method of coding sensory (or other) information in the nervous system. In searching for this type of coding, one must identify correlation between spike trains that exceeds that resulting from the stimulus-related variations in each spike train. It is also necessary to show that a decoding mechanism for spiketrain correlation exists among the neurons upon which the experimentally observed neurons synapse. We do not have such information for the particular example of "candidate code" described above. Both spatial and temporal sequence of incoming synaptic activation have, however, been shown to be important in determining the firing probability of a neuron. Experimental evidence for sensitivity to synaptic sequence can, in part, be found in Hall (1965), Moushegian et al. (1964), and Rose et al. (1966). Theoretical calculations of the effect of synaptic sequence on the resulting PSPs have been carried out in part by Rall (1964), MacGregor (1968), and Fernald (1970).

Perhaps the most interesting application of these approaches to the study of neuronal grouping is in experiments with plasticity of the nervous system. The basic experimental design examines the correlation structure of spike trains as a function of a conditioning paradigm. Thus, it is possible to measure whether the strength or the nature of the interconnections between the observed neurons is varied by the conditioning procedure. Experiments at our laboratory have shown that such changes of interactions between neurons do take place (W. Kristan, personal communication). As such studies progress, it may well turn out that the functional grouping of neurons is a dynamic property and that association of neurons depends on past usage as well as present task. Just as a picture of the nervous system in terms of single-neuron function has emerged, we may hope that the next few years will bring an understanding of neural groupings as functional elements of the nervous system.

58 Data Transmission by Spike Trains

C. A. TERZUOLO

IN THIS PAPER I summarize some of the data and the main conclusions on the subject of data transmission in the nervous system as gleaned from the work of Drs. Bayly, Knox, Poppele, and myself. First, I provide an outline of the approach to be used. Then I touch upon the following topics: 1) The information-carrying parameter of nerve-impulse

- trains. 2) Demodulation of the information by biological systems
- (nerve cell and effector muscle).3) The implication of "regular" and "irregular" carrier rates for data transmission in single and parallel channels.

Systems-analysis approach

In selecting the methodological approach for determining the time-dependent characteristics of neuronal systems a few considerations are relevant. First, it can be contended

that communication between the organism and its environment occurs essentially by way of continuous signals. In receptor organs, for example, the potential changes known as generator potentials are the first neuronal correlate of the input signal. The subsequent transformation of this continuous voltage into a discontinuous process, namely impulse activity, does not preclude the possibility of using the techniques of systems analysis that were developed for deterministic and continuous linear systems. To this end, deterministic input functions can be used and the output can then be derived by measuring a certain parameter or parameters of the spike train or by demodulating the information by means of procedures similar to those utilized by the organism in transforming impulse activity into continuous signals. With either approach, sample averaging is often required for the purpose of extracting the deterministic properties of the system under study. Indeed, the variables affecting the parameters responsible for neuronal activities combine, in most instances, to produce outputs that are essentially probabilistic in nature. This is particularly true when the occurrence time of individual action potentials is con-

C. A. TERZUOLO Laboratory of Neurophysiology, University of Minnesota Medical School, Minneapolis, Minnesota

sidered. However, the underlying deterministic properties of the system are still definable, by using systems analysis, if the distribution of output states is such that no distortions attributable to nonlinearities are present at the output. Sample averaging removes the effects of variables that are either intrinsic to the system, or result from changes in inputs that cannot be controlled by the experimenter. These effects are, therefore, equated with "noise."

To be sure, the approach will not permit, when spike trains are considered, to predict the time of occurrence of individual spikes if "noise" is present. However, when considering the integrative aspects of nerve functions in vertebrates it would seem that: 1) the time over which a spike can occur, in any given neuron, is only a small fraction of the integration time of the subsequent neuron; and 2) a large number of input channels usually converge upon central neurons, whereby only the density of spike occurrence within these converging channels is significant.

The experimental situation, when dealing with spike trains, can therefore be summarized as follows:

When the input is deterministic and continuous, as for a sinusoidal modulation, the analysis is designed to extract the modulation component present in the spike train. By measuring the gain and phase relations between this modulation component, which is contained in certain parameters of the spike train (see below), the time-dependent characteristics of the underlying deterministic properties of the system can be rigorously defined within the limits of its linear behavior. These results can then be used either to develop a model or to test the validity of previously proposed models.

The information–carrying parameter of nerve–impulse trains

When confronted with a device whose output is in the form of a train of pulses, a choice must be made about the parameter to be quantitated for the purpose of recovering the information applied at the input. Indeed, several related but nonequivalent parameters can be described for a train of pulses. When the device considered is a biological system, the choice of the output parameter should take into account the fact that the train of nerve impulses is going to be the input to other biological systems. Therefore, the parameter to be measured cannot be chosen arbitrarily, provided that we are interested in describing the way in which signals are transformed and operated upon in the nervous system. This restriction imposes the necessity of defining the biologically relevant, information-carrying parameter or parameters of nerve-impulse trains, namely those used in the process of data transmission between neurons and between neurons and effector organs. A review of the work by other authors on this subject has been recently provided by Perkel and Bullock (1968).

For our purpose, it will be sufficient to consider impulse rate (defined as the number of events for a given unit of time), intervals between impulses, and instantaneous rate. The latter is defined as the reciprocal of interval, and it is therefore equivalent to impulse rate only in the special case of an unmodulated pulse train. In a recent paper (McKean et al., 1970) data were presented that define the difference between the information carried by the parameters in question (see also Knight, 1969). Briefly, if a voltage-to-frequency converter is used, the relation between the sinusoidal input voltage to this device and the output pulse train are different, depending on whether impulse rate or intervals are considered. In the case of impulse rate (Figure 1, dashed line) the gain is constant and there is no phase shift, regardless of the input frequency.

Gain is defined as 20
$$\log_{10} \frac{\text{output}}{\text{input}} K$$

where K is a constant. On the contrary, when instantaneous rate is measured at the output, the gain and phase relations as a function of modulation frequency become dependent on the average pulse rate, as shown in the solid curves of Figure 1.

Starting from this observation, two experiments that are formally equivalent can be designed. It is possible to measure either the transmembrane potential changes resulting from synaptic activity in a neuron receiving a frequency-modulated impulse train, or the tension changes of a muscle activated by applying a frequency-modulated pulse train to its nerve can be measured. The second experiment has the advantage that the output, muscle tension, is a behaviorally meaningful parameter. By using different input carriers (carrier being defined as the unmodulated pulse rate), one can establish if the phase between the input sinusoid to the voltage-to-frequency converter and the tension output is or is not dependent on the carrier rate. By stimulating all channels in unison, the experimental design makes a multiplechannel system equivalent to a one-channel system, therefore avoiding the effect to be observed in a population of voltage-to-frequency converters as described by Knight (1969).

Figure 2 shows the results of one such experiment. Four

FIGURE 1 Difference between rate and interval parameters. The Bode plots describe the relations of the gain (A), in decibels, and the phase (B), in radians, between a sinusoidally modulated voltage applied to a voltage-to-frequency converter and the pulse rate (dashed line) or the instantaneous rate (solid curve) parameters. \vec{p} is the average carrier rate. Fully explained in the text.

carrier rates were used. There is no appreciable difference in the phase of the output tension for all the carrier rates. Therefore, impulse rate or the average change around the carrier rate, rather than the interval between impulses, is the biologically relevant parameter.

Demodulation of impulse frequency by biological systems

The above experiment also provides, within the limits of linear behavior of the systems involved, the transfer function between impulse rate and behavioral output (changes in muscle tension). The phase plot of Figure 2 is characteristic of a process of low-pass filtering. The same behavior has also been observed at the output of medial geniculate neurons (Maffei and Rizzolatti, 1967) and in the isolated sensory neuron of the crustacean stretch receptor (Terzuolo and Bayly, 1968). In the latter case, the low-pass filtering properties could be ascribed to the synaptic processes combined with the cable properties, because the dynamic characteristics of the encoder system were known and therefore could be subtracted from the Bode plot describing the input-output relation of the cell (see below).

Examination of the harmonic distortions and of the power spectrum in the nerve-muscle experiment proves that the recovered information can be free of distortion if the frequency of the input signal, or information, is low with respect to the carrier rate. This agrees well with the view expressed above that the demodulation process is equivalent to low-pass filtering. In fact, under the above conditions, the input information is simply a variation in the average, or DC value, of the pulse train and stands isolated

FIGURE 2 Absence of dependency between the phase angle of the sinusoidally modulated muscle tension and the average impulse frequency of the motor nerve in decerebrate cat. A sinusoidally modulated pulse train was used to

stimulate the distal end of the cut gastrocnemius nerves. Stimulus carrier rates were 14.5 (\times), 19.4 (pyramid), 29 (+), and 37 (inverted pyramid) pulses per second.

in the spectrum (Bayly, 1968). Provided that the filter time constant is short with respect to the modulating frequency and long with respect to the period of the carrier, recovery of information by low-pass filtering removes sideband frequency components that occur at each multiple of the carrier rate (Figure 3). The demodulated information is therefore free from distortion if the modulation depth and frequency are suitably restricted. As the frequency of the input information is increased with respect to that of the carrier rate, sample averaging becomes necessary if a single input channel is used. The results obtained by this procedure, however, are similar to those obtained, without need for averaging, when parallel input channels are used, or the mean carrier rate is increased (see next section of this chapter). Also, the process of demodulation is formally equivalent whether one considers the transfer of information between nerve cells or between a neuron and an effector muscle (McKean et al., 1970). In the first case, the filtering process results from characteristics of the postsynaptic potential; in the nerve-muscle preparation, the filtering process results from the characteristics of the contraction and relaxation processes. In both instances, the output (transmembrane potential change or muscle tension) is a function of the number of input impulses occurring in a given unit of time (the input-output relation at the neuromuscular junction being one-to-one). The averaging characteristics are determined, as in a low-pass filter, by the impulse response of the filter, which, in biological systems, is given either by the form of the postsynaptic potential or by the time course of the muscle twitch.

The operation of a low-pass filter can be demonstrated by

an electrical analogue (resistance-capacitance [RC] network). Figure 4 shows the response of a filter when a sinusoidally modulated train of pulses is applied at the input. Note the similarity of this response to the muscle-tension response in Figure 2, and that this, too, is independent of carrier rate.

This conceptual model of low-pass filtering for the process of demodulation in the nervous system (cf. also Stevens, 1968) is equally applicable to both chemical and electrical synapses. Models that utilize an RC filter to mimic the time of decay of the postsynaptic potential have been used by several authors to investigate input-output relations under several conditions (cf. Segundo et al., 1968).

When the dynamic characteristics of the low-pass filtering process are specifically considered, additional implications become obvious. First of all, the averaging time of the filter must be short with respect to the frequency content of the input signal if this must be recovered unchanged (Bayly, 1968; Terzuolo and Bayly, 1968). Second, there will always be a restriction on the dynamic range of the information transfer (upper-modulation frequency), no matter how high the input and output carrier rates. Moreover, the gain of the demodulated signal will depend on both input and output carrier rates.

Although these points have been discussed previously (Terzuolo and Bayly, 1968), it is more relevant in the present context to stress that, given certain low-pass characteristics of the demodulation processes, a continuous function can be obtained at the output even when the input pulse train is modulated by more than 100 per cent, at least for certain frequencies of modulation (McKean et al., 1970).

FIGURE 3 Demodulation of a "regular" impulse train by low-pass filtering. F_m : modulation frequency, F_0 : carrier rate. Note that the reduction of the magnitude at frequen-

cies above the modulation frequency depends upon the characteristics of the low-pass filter. (Modified from Bayly, 1967.)

FIGURE 4 Low-pass filter behavior. The Bode plots describe the relation between the signal applied to a voltageto-frequency converter (sinusoidal voltage) and the output of an RC filter, which demodulated the frequency-modulated pulse train produced by the voltage-to-frequency con-

verter. Gain, in decibels, is shown in the upper plot, while the phase angle, in degrees, is seen in the lower plot. Carrier rates of 10 (\times) and 20 (pyramid) pulses per second were used. Note that the gain and phase of the filter output are independent of the carrier rate (as in Figure 2).

Figure 5 illustrates this point. A filter with characteristics similar to those of the nerve-muscle preparation was used. In A, the input to the filter was a sinusoidally modulated pulse train. Separate bursts of pulses do lead, however, to similar results (only the gain being different), even if such bursts are substantially shorter than the period of the input sinusoid and if the interval between pulses, within the burst, is equal to that of A (Figure 5B). This fact demands the use of much restraint when considering the possible significance of patterns of unitary impulse activity. Also, several parameters of the pulse train become significant, under these conditions, for the recovery of the signal at the output of the low-pass filter. These parameters (duration of the burst, interval between bursts, phase relation between the burst and the input signal) are significant in the present context only when related to the frequency content of the input signal and the dynamic characteristics of the demodulation process (receiver). They cannot be considered as separate "codes" (see Perkel and Bullock, 1968) when they are found, under physiological conditions, in the same channel (the case of spinal motor neurons is a well-demonstrated instance, cf. Rosenthal et al., 1969). Indeed, as emphasized above, a knowledge of the dynamic characteristics of the receiver is a necessary condition for defining the signal-carrying parameter or parameters of impulse trains.

One more point. The model is consistent with the obser-

vation that input patterns may be significant in determining the output of the cell *when* the voltage changes produced by each presynaptic impulse are a significantly large portion of the voltage difference between resting level and threshold. This has indeed been shown under certain experimental conditions (Segundo et al., 1963). Also, presynaptic and postsynaptic changes are known to be capable of altering the effectiveness of synaptic inputs (see Eccles, 1964, for a review). This condition may also occur when more than one input is activated at the same time, owing to the fact that changes in membrane properties caused by the activation of an input can affect the postsynaptic potential caused by another input (Rall, 1964; Terzuolo and Llinás, 1966). These situations are still compatible with the low-pass filter model, as only the filter properties, or the contribution by a given input, is eventually different at any one time. However, in some of these cases, specific parameters of impulse trains can acquire an overriding biological significance (cf. Perkel and Bullock, 1968).

Of more general interest, although seldom considered, are the changes that the demodulated information may undergo during the encoding process as a consequence of the dynamic characteristics of this encoder system (spikeproducing processes). Neurons, in general, can be conceptually subdivided into two systems connected by a cable, as in Figure 6A. The adequacy of this conceptualization has

FIGURE 5 Behavior of a low-pass filter to a sinusoidally modulated and to a discontinuous pulse train. Upper trace in both A and B is the input voltage to the voltage-to-frequency converter; the second trace is the resulting train of pulses that is actually fed to the RC filter; the bottom trace is the output of the filter. In A, the train is sinusoidally modulated. In B, only a burst of equally spaced pulses was used. The modulation frequency was 10 Hz. The filter characteristics are similar to those of the nerve-muscle preparation whose frequency response is shown in Figure 2. Fully explained in the text.

been verified experimentally in the isolated neuron of the crustacean stretch receptor, in which the dynamic properties of the over-all neuron, as well as those of each of its component systems, were first studied (see Terzuolo and Knox, 1970), and in the eccentric cells of the *Linulus* eye (Dodge et al., 1968). By applying a sinusoidal current through a microelectrode placed inside the soma, the transfer function described by the Bode plot of Figure 6B was obtained for the encoder of the crustacean neuron. The gain and phase are not flat through the range of input frequencies (Terzuolo et al., 1968). Moreover, the behavior is dependent on the carrier rate even if impulse frequency, rather than instantaneous frequency, is the parameter measured.

Similar carrier-dependent behavior is also observed in the secondary endings of muscle spindles but not in the primary endings (Poppele and Bowman, 1970). Moreover, the differences in the response of different neurons to a current pulse, although in most cases not expressed in the form needed to define the frequency response characteristics of their encoder systems, certainly indicate that these characteristics vary from cell to cell (cf. Eccles, 1964). Finally, the dynamic properties of an encoder model have been shown to be influenced by such factors as: 1) the amount of membrane that is antidromically invaded; 2) changes in time constant and space constant; 3) amount of local response; and 4) accommodation (Bayly, 1967). It is our view, therefore, that the properties of this system are a most significant factor in determining functional differences between neurons.

Implications of "regular" and "irregular" carrier rates for data transmission in single and parallel channels

The presence of a "regular" rate of firing, when no timevariant function is applied at the input, was considered above as the equivalent of the carrier rate in a man-made communication system. It is obvious, however, that the average rate of the unmodulated impulse train, that is, its DC component, can be utilized by the nervous system to sense or impose levels of activity. This is certainly the case for those sensory systems subserved by receptors whose impulse frequency is proportional to the applied stimulus under steady-state conditions. However, distributions of impulse intervals vary in different systems and even within the same system under different conditions. While in some cases it is well known that the interval distribution is Gaussian, in other instances Gamma or Poisson distributions are present (as examples, see Gestri et al., 1966, and Knox, 1969, 1970).

One may therefore ask what influence the different types of carriers have on the signal that is transmitted by the different types of channels and what the consequences might be for the subsequent demodulation of the information by low-pass filtering.

To answer these questions, a common representation for all types of spike trains is desirable, and preferably in a form amenable to signal analysis in the frequency domain. The power-spectral density satisfies these requirements, because only this representation can be used for "irregular" carriers (the properties of these spike trains being definable only probabilistically [Perkel et al., 1967a, 1967b; Moore et al., 1968]).

For "regular" carrier rates, the spectral density shows that the DC component is accompanied by a single component at the modulation frequency, without multiples or harmonics. In addition, the spectrum contains components at all harmonics of the carrier rate, each accompanied by a set of adjacent sideband components that are displaced from these harmonics by multiples of the modulation frequency (Bayly, 1968), as shown in Figure 3. This situation places restrictions, when a single input channel is used, on the possibility of demodulating high-frequency information by low-pass filtering. Indeed, as the frequency of the input information approaches the carrier rate, distortions will arise from the

FIGURE 6 Data transmission between neurons. A: Schematic diagram of the process of data transmission between neurons. The presynaptic impulse train F(t) is demodulated by a process of low-pass filtering that leads to the transmembrane potential change $P_s(t)$. This is the input to the second system which encodes $P_s(t)$ in a frequency modulated output train $F_1(t)$. B: Dynamic properties of the two systems described in A. The neuron is the sensory cell of the slowly adapting stretch receptor organ of Crustacea. The input of the cell was a sinusoidally modulated impulse train, produced by stimulating the inhibitory axon of the cell. The

lower sidebands of the carrier component, because these first enter the filter passband (Bayly, 1968). Time and sample averaging must therefore be used experimentally to recover the applied information. In the central nervous system, however, parallel channels are available. The convergence of these input channels upon the same cell results in an effective increase in the average carrier rate. Therefore, while the information conveyed by any given channel may be ambiguous and distorted for a given combination of input frequency and carrier rate, the convergence of these inputs permits the cell to perform a sample average (Bayly, 1968;

output measured was instantaneous frequency. Gain, in decibels (open circles), and phase, in radians (closed circles), are plotted versus the modulation frequency, the carrier rates of the input-and output being the same (10 impulses per second). The broken lines describe the gain (g) and the phase (p) of the encoder system alone, as obtained by applying a sinusoidally modulated current through a microelectrode placed inside the soma of a crustacean neuron. These values must be subtracted from the experimental points to determine the transfer function of the demodulation process. (Modified from Terzuolo and Bayly, 1968.)

Terzuolo and Bayly, 1968). The information can therefore be immediately available to the postsynaptic cell with little or no distortion (Poppele and Terzuolo, 1968; Maffei, 1968).

An example of the effect of increasing the carrier rate in a single channel is shown in Figure 7, and Figure 8 shows the effect of parallel channels converging upon a single motor neuron. Actually, an estimate can be made of the improvement in the signal-to-noise ratio to be expected as a function of the number of input channels.

If the carrier rates of the individual channels differ, then
an improvement in the signal-to-noise power ratio, S/N, occurs because of the dispersion in frequency of the spectral components representing the distortion. In this case, and if the modulation depth is low, it may be shown that S/N increases as the number of channels increase (Bayly, 1968). If the carrier rates are identical and the channels are independent, improvement in signal-to-noise power ratio may still be realized. For a two channel system, S/N is given approximately by

$$S/N = \frac{\pi^2(1-\alpha)^2}{\sin^2(\pi-\pi\alpha)}$$

if α , the percentage modulation, is low.

FIGURE 7 Linearization of the spindle output by the increase of the average carrier rate. The output from a primary ending of a gastrocnemius muscle spindle was modulated by stretching the muscle sinusoidally in the presence and in the absence of gamma activity. Upper plot: Spindle response in the absence of gamma stimulation. Note the absence of activity throughout one-half of the cycle. Middle plot: Spindle response in the presence of gamma stimulation of 28 pulses per second. Ordinate: changes in spindle discharge frequency in pulses per second. Lower plot: averaged data points of the input, with the fundamental frequency fitted to these points. Ordinate: microns of displacement. (From Rosenthal et al., 1969.)

When discussing multiple channels, it should be realized that, irrespective of the nature of the carrier in any given channel and its rate, the combined activity quickly tends to resemble that of a random Poisson process (Cox and Lewis, 1966), if sufficiently large numbers of independent channels are utilized in the absence of an applied input. Therefore, this type of carrier may be taken as being more general than the preceding one. Not surprisingly, the power spectrum of the random spike train shows that there are no components attributable to the carrier rate, λ_0 , but only a large DC component whose power is proportional to λ_0^2 and a continuum of noise components whose power is proportional to λ_0 (Knox, 1969a, 1969b). In the case of sinusoidal modulation of the mean rate of impulse occurrence, a single component appears in the spectrum, the power of which is proportional to the modulation amplitude, λ_m , squared (Figure 9). Demodulation of the random spike train is therefore possible by low-pass filtering. However, there will always be distortion present at the output of the filter because of the continuum of the noise components. As discussed by Knox (1969, 1970), if the filter passband is f_B , the signal-to-noise power ratio is given by

$$S/N = \alpha^2 \lambda_0 / 4 f_B$$

for modulation frequencies much less than the reciprocal of the pulse width, and where $\alpha = \lambda_m / \lambda_0$. Notice that this expression applies equally to single random spike trains and to

FIGURE 8 Sample average by a postsynaptic neuron resulting from the convergence of parallel input channels. Upper trace is an intracellular recording of transmembrane potential of a gastrocnemius motor neuron during sinusoidal muscle stretch (lower trace). Stretch frequency was 4 Hz. About ten sweeps are superimposed to show that the input information (sinusoidal stretch) becomes immediately available to the postsynaptic cell because of the spatial averaging provided by the convergence of parallel channels. This, in spite of the fact that the information contained in each channel is only partial and ambiguous (upper plot of Figure 7). Fully explained in the text. (Poppele and Terzuolo, unpublished.)

FIGURE 9 Power spectral density of the random pulse train. Sinusoidal modulation of the mean rate of occurrence, $\lambda(t) = \lambda_0 + \lambda_m \cos \omega_m t$, impulses per second, introduces a single component at the modulation frequency. In the ab-

sence of modulation, the spectrum contains the DC and band limited noise components. (Modified from Knox, 1969.)

the combined activity of multiple, independent channels, because, if we suppose for simplicity that λ is constant, then λ_0 can represent the sum of the individual channel carrier rates. The relationship shows the trade-offs available between number of channels, carrier rates, and filter passbands for any given signal-to-noise ratio. As an example, for $\alpha = 0.5$, $f_B = 16$ Hz and S/N = 10, $\lambda_0 = 2300$ impulses per second. This illustrates the disadvantages of using a single input channel with a random carrier.

However, the rate shown above is well within the physiological limits of systems that utilize parallel channels. For instance, all the primary endings from muscle spindles are said to distribute information to the entire motor neuron population belonging to the same muscle (Mendell and Henneman, 1968). In the gastrocnemius muscle of the cat, as an example, there are roughly 140 spindles (Swett and Eldred, 1960), so an average carrier rate of 20 impulses per second could satisfy the above requirement. This rate is well below that which can be attended under gamma activity. Moreover, it is likely that randomness, even in the presence of a forcing function affecting all spindles alike (e.g., stretch), may be insured by the random action of gamma motor neurons upon the individual spindles.

Conclusions

In closing this brief review of some of our findings, I would like to stress that the study of the dynamic properties of single neurons alone, although a necessary step in the quest for the operational principles utilized by the nervous system, might not be sufficient for the formulation of models capable of accounting for relatively complex functions. The properties of populations of nerve cells could indeed exceed those of the individual elements of the population. Confronted with the task of "explaining" the input-output relations of the nervous system in terms suitable to the formulation of quantitative models, the choice of the experimental approach and data-processing techniques often acquires an overriding importance.

In several physiological functions the use of systemsanalysis techniques and the approximations to linear analysis, for the purpose of defining the time-dependent characteristics of component systems, is now warranted over a behaviorally meaningful portion of the operational range of the systems involved. Only by defining such dynamic characteristics in relation to behaviorally meaningful outputs can we eventually acquire an appreciation of the significance, or insignificance, of parameters that are presently utilized only because they can be measured by available techniques. It is likely that the emphasis placed on some of these parameters might not be justifiable in every case. For instance, we have presented here data showing that certain details of given patterns of impulse activity may have no functional significance, owing to the dynamic characteristics of the system that receives such patterns. (For a review on this subject, in which those data supporting a different viewpoint are also considered, see Perkel and Bullock, 1968.) Conversely, certain properties that have not yet been adequately explored may be present.

For instance, the possible role of neurons as interface devices, instead of only summing integrators, is rarely considered. The dynamic properties of the encoder alone could provide for this possibility, as it is not inconceivable that the encoder could act to transmit information selectively within a certain frequency range, thereby transforming the output of one system into a form compatible with the function of another. Indeed, it seems unlikely that the output of one neuron is in a form appropriate for all those systems to which it distributes. The existence of such neurons may be now suspected, given the observation that only pyramidaltract fibers apparently impinge upon certain spinal cord interneurons (Kostyuk et al., 1968).

If confirmed and extended to other cells, this observation can be highly significant. One would expect, in these cases, a highly different behavior from that observed in integrative neurons, such as the alpha motor neuron, in which uniform populations display a linear input-output relation, in terms of phase and relative gain, within a large frequency range (Poppele and Terzuolo, 1968; Rosenthal et al., 1969). Similar frequency independency of the input-output relations was also observed in neurons of the dorsal spinocerebellar tract (Jansen et al., 1967) over a modest frequency range. This behavior can easily be accounted for on the basis of the arguments developed above concerning the signal-carrying parameter of nerve-impulse trains and the demodulation processes by low-pass filtering. This simplicity is also found by comparing psychophysical measurements to unit responses in the somatic system, and has led Mountcastle (1967) to suggest that signal transformation in this system is entirely linear. In this context, one may notice that when "regular" carrier rates are present, a condition that appears to be particularly advantageous in a few input channels, the presence of a cascade of suitable low-pass filters (successive synapses) may provide a means of removing those distortions of the input signal that are the result of the presence of the carrier (sidebands).

Acknowledgments

It is a pleasure to thank Drs. Bayly, Knox, McKean, Poppele, and Rosenthal for reading the manuscript critically and suggesting several improvements. The research program is supported by PHS Grant NB 2567, and by the Air Force Office of Scientific Research Grant AF-AFOSR-1221-67.

ASPECTS OF MOLECULAR NEUROBIOLOGY

Neuronal dynamics: Synaptic release, in a complex cleft, of transmitter, trophic, and macromolecular materials that modify the electric, metabolic, and genetic expression of the postsynaptic neuron; linkage between membrane componentry and genetic machinery that results in induction of enzyme synthesis and in changes of initial segment excitability; and production of vesicular organelles and enzyme cargo, translocated down the axon possibly by chemomechanical energy-coupling on microtubules. Prefatory Remarks on Aspects of Molecular Neurobiology

FRANCIS O. SCHMITT

THE TERM "molecular biology" was initially popularized by William T. Astbury, the first professor of biomolecular structure, to denote that branch of life science which attempts to determine the molecular parameters of cell structure and function (Hess, 1970). Before electron microscopy, molecular biology was based primarily on X-ray crystallography and polarization optics; these and other physical methods, used in what was then called "colloid" science, helped deduce molecular parameters, particularly with regard to protein effectors of cells. Two decades later, DNA and RNA were characterized chemically and structurally, thereby ushering in the era of molecular genetics, with its concepts of transcription and translation in biosynthesis. With this breakthrough, the term "genetics" was broadened beyond the confines of problems of heredity as such. The implications of molecular genetics grew so large that it became widely identified with the parent field of molecular biology.

In the Second Intensive Study Program of the Neurosci-

FRANCIS O. SCHMITT Chairman, Neurosciences Research Program, Massachusetts Institute of Technology, Brookline, Massachusetts

ences, molecular neurobiology was considered from the broad purview of the molecular basis of the structure and function of brain cells and their organization into the systems and subsystems of the central nervous system. The coverage was not meant to be systematic or encyclopedic; for example, it included relatively little systematic neurochemistry, particularly that of the qualitative and the quantitative "What's-there-and-how-much?" kind. The aim was to be selective: it was not merely to deal with the brain as another tissue-like liver or kidney, which have special patterns of metabolism-but to be concerned especially with cellular processes that are unique to the brain; with phenomena that underlie the development of the brain in all its intricate circuitry; with the molecular basis of bioelectrical events, e.g., impulse propagation in axons and in neuronal nets; and, finally, with processes that confer plasticity, such as might provide a basis for learning and memory.

The lectures on molecular neurobiology articulated the current status of selected topics, suggested fruitful strategies of research and experimentation, critically examined current dogmas, however venerable and established, and asked questions that might open new avenues of research, especially to investigators who prepared for this inflectional point in the history of science by becoming proficient in both physical biochemistry and neurobiology.

Contributions to neural development at the molecular level were made by various speakers and participants in this symposium; therefore, there was substantial integration with the symposium on Developmental Neurobiology, organized and chaired by M. V. Edds, Jr.

In addition to the most obvious themes of molecular neurobiology already mentioned, the overriding problem of the molecular basis of learning, storage, delocalization and retrieval of memory, and other "higher" nervous functions were considered in a lower key. No formal lectures dealt with subjects such as the biochemical inhibition or stimulation of memory processing or the attempted transfer of memory or savings by administration of material obtained from trained animals. To some extent these topics were treated in the symposium on Determinants of Neural and Behavioral Plasticity, organized and chaired by R. Galambos.

The plenary and symposium lectures are conveniently grouped under four major headings: membranes; neuronal junctions; neurobiosynthesis; and neuroplasmic transport.

MEMBRANES AND INTERCELLULAR INTERACTION Important ideas about the molecular organization of neuronal membranes are presented by M. Delbrück, who discusses new advances in specific ion transport in model membranes. M. Eigen provides a penetrating and highly original analysis of the mechanism by which ions as similar physically as Na⁺ and K⁺ may be distinguished in model membrane systems and, presumably, also in natural membranes; this hypothesis may well prove to be the answer to this central problem that has long eluded biologists, biochemists, and biophysicists. Application of physical methods, particularly electron spin labeling, are presented by H. M. McConnell. Molecular mechanisms underlying impulse propagation, as deduced from optical studies (birefringence, light scattering, fluorescent probes) conducted chiefly in his own laboratory, are discussed by R. D. Keynes.

NEURONAL JUNCTIONS The molecular biology of the synapse is portrayed at the electron-microscope level by J. D. Robertson and F. E. Bloom. Synaptic membranes are presumably sites of gene-directed molecular recognition that determines the ordering of neuronal circuitry in the developing central nervous system S. H. Barondes presents the view that glycoproteins and glycolipids, especially carbohydrate terminal residues, are responsible for this recognition. The biochemical aspects of neuronal junctions are given by V. P. Whittaker, with special reference to studies of isolated synaptosomes. Interwoven with the concepts of the synapse are current views about the synthesis, release, and mode of action of transmitters, presented by L. L. Iversen.

Glial membranes and glial-neuronal interaction are considered by R. P. Bunge, who, after dealing with the general phenomenon of neuronal ensheathment by glia and with permeability and bioelectrical parameters, concludes that, although not indispensable to neurons (under specialized or experimental conditions), glia are important regulators of neuronal activity.

BIOSYNTHESIS AND GENE EXPRESSION IN BRAIN CELLS Comparative studies suggest that the portrayal of the prototypical vertebrate neuron given in textbooks is not a good model for the neurons of invertebrates, which represent some 95 per cent of the known animal species. M. J. Cohen points out that the soma is not so involved biochemically and physiologically in the neurons of invertebrates (at least in insects) as in those of vertebrates, which may explain why the former show more stereotyped behavior than do the latter.

E. M. Shooter discusses brain-cell organelles in the framework of the synthesis of products, chiefly proteins and enzymes, of gene expression. He also considers the effect on the regulation of gene expression by internal stimulation, e.g., by hormones and by the nerve growth factor, which has been the object of intensive study in his laboratory.

A. L. Lehninger authoritatively characterizes mitochondrial function, especially as manifested in brain cells, and offers cogent reasons supporting the view that mitochondrial membranes, readily available for experimentation, may represent a fruitful model of the neuronal membrane.

NEUROPLASMIC FLOW AND FAST TRANSPORT The subject of slow neuroplasmic bulk flow and fast specific transport is portrayed in its broad neurobiological setting by P. A. Weiss, whose work over the last three decades has revolutionized our concepts of neuronal dynamics. Following his overview, P. F. Davison analyzes the possible role in these phenomena of the fibrous proteins, microtubules, and neurofilaments.

Correlation and summational essays

P. D. Nelson assesses the impact of the discussions on concerns at the higher levels of neurophysiology and psychology.

As organizer and chairman of the symposium on Molecular Neurobiology, I provide a summational essay.

60 Lipid Bilayers as Models of Biological Membranes

M. DELBRÜCK

Real membranes

WHEN WE TALK about biological membranes, we must recognize, first, their unity in some general features and, second, their enormous diversity in many specific features.

The most obvious aspects of unity are their thickness, around 70 Å; their composition, protein and lipid; the barrier they present to permeation; and the property of fragments of membranes to round up into vesicles and of holes to seal.

The most obvious features of membrane diversity are variations in thickness; great variations in the protein-tolipid ratio; great variations in the kinds of lipid and kinds of protein; great variations in permeability; and infinite variations in function.

SEVERAL KINDS OF NATURAL MEMBRANES Glancing briefly at the varieties of function, we have, first, a membrane enclosing every cell; this is the *cytomembrane* or plasmalemma, which exerts chemostatic controls on the interior and transmits numerous signals. It is characterized by the presence of glycolipids (Rouser et al., 1968). There is the *double membrane surrounding every nucleus*. This membrane has, in many cases, been shown to have "holes," seemingly violating the principle that the real membranes minimize their perimeter. The contradiction is, however, only apparent, because the perimeters of these holes are not perimeters of the membrane; they are places at which the nuclear membrane folds over (Figure 1).

FIGURE 1 Nuclear double membrane with "holes." The perimeters of the holes are not perimeters of the membranes, but are places at which the membrane folds over.

There is the *myelin sheath*, an elaboration of the cytomembrane of the glial cells associated with nerve fibers. Perhaps this membrane is the one of least sophistication and the simplest function—that of electrical insulation. Its asymmetry is more conspicuous than that of most other mem-

M. DELBRÜCK Division of Biology, California Institute of Technology, Pasadena, California

branes. Because it is multilayered in a very regular way, it has been a favorite subject for physical studies by means of low-angle X-ray diffraction.

There is the mitochondrion, with its interesting construction involving two totally different kinds of membrane, the inner one and the outer one. The inner one forms the cristae and is perhaps the most complex of all membranes. It is the carrier of the complicated machinery coupling the energy derived from respiration to the synthesis of adenosine triphosphate (ATP). It is, perhaps, unfortunate that such a disproportionately large share of the efforts of the biochemical and biophysical fraternities is spent on this superelaborate structure (and on the analogous chloroplasts), rather than on those membranes that show simpler specializations. The mitochondrion as a whole, as Lehninger explains in his chapter in this volume, is thought to have been derived in a very distant way from originally free-living bacteria, which, in the course of evolving, have become stripped of a great number of functions. The principal argument in favor of this hypothesis derives from some similarities of this inner membrane with the cytomembrane of bacteria. These similarities consist of the following: (1) both are the locus of oxidative phosphorylation; (2) both contain a specific phospholipid, diphosphatidyl glycerol (DPG); and (3) both lack sterols. As to DPG, it is an interesting lipid, which carries two negative charges in close proximity and, therefore, is prone to conformational changes when binding doubly-charged positive ions, such as Ca++ (Shah and Schulman, 1965). The absence of sterols is a characteristic that appears to be limited to the inner membrane of mitochondria and, possibly, to the lamellar membrane of chloroplasts (Mercer and Treharne, 1965). All other membranes of plants and animals contain ergosterol or cholesterol, or some closely related compounds.

The outer membrane of the mitochondrion is perhaps a close relative and an elaboration of the *endoplasmic reticulum*, the locus of many synthetic activities in the cell. Both the outer membrane of the mitochondrion and the endoplasmic reticulum are characterized by the absence of glycolipids.

In a different direction of sophistication, we should mention the excitable membranes of the *nerve axon*, of the *muscle fiber*, and of their synaptic specializations. Here the most conspicuous aspect is the high degree of modifiability, in an all-or-none fashion, suggesting a very high degree of cooperativity between the elements of the membrane. It seems probable to me that the changes in state observable in these types of membrane are analogous to phase transitions of thermodynamics. These phase transitions, here occurring in two-dimensional objects, would be governed by somewhat different rules from those of ordinary thermodynamics. The rules have, as yet, been incompletely worked out. An important specific model for the functioning of nerve excitation has been presented (Adam, 1970). Finally, we should mention the most "clever" membranes, which can be found in the *specific portions of sensory cells*, where they are attuned to the transduction of various kinds of stimuli. These systems can be triggered to change their state and thus give a macroscopic response by absolutely minimal inputs. The input may be a quantized one—a single molecule or a photochemical change in a single molecule, in olfaction and vision, respectively—or it may involve minimal changes in some continuous parameter, as in mechanical, electrical, or thermal stimuli.

PERMEATION Let us stick to the simpler aspects and concentrate on permeation. Here we owe to the work of physiologists (Stein, 1967) a general classification:

Simple permeation, largely determined by the partition coefficients of the solutes between aqueous and lipid phases, and by diffusion within the lipid phase.

Facilitated permeation, involving carriers or pores or, perhaps, as we shall see, in some cases "carried pores." This kind of permeation is characterized by the phenomena of saturation and competition.

Next in sophistication we have *coupled carrier transport*, involving cotransport or countertransport of two species owing to the fact that the mobility of the carrier depends on more than one ligand. This kind of transport can cause motion of one component against its electrochemical gradient, by coupling it to the transport of another component that moves with its gradient.

We must and do have, in addition, *primary active transport* coupled to energy consumption in a manner that is not completely understood in any one case. Perhaps the closest to a complete understanding has been achieved in sugar transport in bacteria, in which it turns out that the transported species is a transiently phosphorylated one (Kaback, 1968).

The approach through the study of lipid bilayers

NAKED MEMBRANES It will take many years and many lines of attack for us to understand the structure and mode of function of all these membranes in their molecular details. The approach that I discuss here is that which starts out with lipid bilayers between aqueous phases and advances by modifying these bilayers in various ways, leading to simulation of some of the functions mentioned. This approach was pioneered by Mueller and Rudin, and to them we owe also the majority of the very interesting modifications of the properties of simple bilayers that can be obtained with the help of a variety of additives.

The simple bilayer is a miraculous structure in itself. It can be formed by smearing a lipid mixture across a hole in a partition separating two aqueous solutions. Under appropriate conditions, the nature of which is not clearly understood, these lipid mixtures thin out to "black membranes," truly bimolecular structures in which the polar heads of the phospholipids face the water phases, and the hydrocarbon chains form a somewhat disordered and liquid layer about 50 Å thick. The disorderliness is an essential feature. It is generally assured, at body temperature, by there being a sufficient number of kinks, cis-double bonds, in the hydrocarbon chains. Also necessary for good membrane formation is the presence of cholesterol or tocopherol or tetradecane or some such neutral compound, for reasons not clearly understood. The membrane part is surrounded by a rim of lipid in the "bulk phase." The structure of this bulk phase has never been characterized. To which of the several possible lipid-water phases (Luzzati, 1968) does it correspond? Or does it retain enough solvent to remain a disordered liquid?

This form of lipid bilayer is under tension, and is mechanically in a metastable state. When the membrane tears, the lipid is swallowed up by the bulk material along the rim of the hole across which the membrane is formed. It does not easily break because a relatively large activation energy is needed to start a tear. The liquidity of the hydrocarbon middle part is essential for giving the membrane plasticity. If the membrane is too stiff, it becomes mechanically fragile. One should appreciate the astonishing disproportions of such a membrane: a membrane 1 mm in diameter and 70 Å in thickness, if scaled up, would correspond to a thin piece of paper 30 feet in diameter.

The so-called surface tension (a few dyne cm^{-1}) of such double layers, measured by bowing them out with overpressuring of the liquid on one side, is not an ordinary interfacial tension. It is a measure of the relative energy of the double-layer versus the bulk phase.

Torn membrane joins the bulk phase, which is distinct from natural membranes, which do not ball up on being torn but retain their thickness. They reduce their contour length to zero by forming vesicles. Natural membranes have a contour tension rather than a surface tension. By contour tension I mean an analogue to the surface tension of liquids. Liquid droplets minimize their surface area, at constant volume, by rounding up to form a sphere. Liquids do so because each molecule tries to maximize its interaction with neighboring molecules of the liquid, and a molecule in the interior of the liquid has more neighbors, and thus more interaction, than one on the surface. Therefore, the liquid tries to have as few molecules on the surface as possible, i.e., it minimizes its surface area and forms a sphere. Analogously, any molecule in a natural membrane has more neighbors if it is in the interior of the membrane area than if it is at the perimeter. Therefore, a natural membrane, if it is constrained to be a membrane of constant thickness, will try to minimize its perimeter. It can do so in three-dimensional space by forming vesicles, thus reducing the perimeter to zero. This is a general feature of fragments of real cellular membranes.

Besides the Mueller and Rudin technique, there are several other methods for forming lipid bilayers. Pagano and Thompson (1967) have described a procedure for forming bilayers in a manner analogous to the formation of soap bubbles: the lipid solution is put into the tip of a pipette, overlayered with an aqueous phase, and blown out under water. Large bubbles can thus be formed that have a bilayer around most of their surface and a cap of bulk material at the top (Figure 2). Such bubbles can be kept in suspension

FIGURE 2 Lipid bilayer bubbles (Pagano and Thompson, 1968). The bubble is suspended in a sucrose gradient and carries a cap of bulk lipid solution. The cap can be penetrated by microelectrodes, and the bubble as a whole can be transferred from one aqueous environment to another.

by being blown into a sucrose gradient. The bubbles can be picked up by being sucked into a pipette and transferred to a different environment, and they can be impaled with microelectrodes. In this way, the bubbles can be used for measuring the permeation of tagged ions (³⁶Cl or ²²Na), and they can be used for measuring the transference of ions during the passage of electrical current (Pagano and Thompson, 1968; Price and Thompson, 1969).

Another interesting procedure has been described by Tsofina et al. (1966). These authors found it difficult to incorporate proteins into lipid bilayers of the type produced by Mueller and Rudin. On the other hand, it has been known from earlier work that *monolayers* of lipids formed at the interface of air and water or at the interface of an organic solvent and water can be strongly modified by the presence of proteins in the aqueous phase. It has been widely believed that this modification is due to a true incorporation of protein into the monolayer. Therefore, Tsofina et al. proceeded to construct bilayers from two lipid-protein monolayers in the arrangement sketched in Figure 3. Bilayers were indeed formed, but it was not actually

FIGURE 3 Bilayer constructed from two lipid-protein monolayers (Tsofina et al., 1966). One monolayer is formed at the interface of the lower aqueous protein solution (Aqu) and the benzene layer containing the phospholipid. A second monolayer is formed at the interface of the benzene phase, and the drop of aqueous protein solution is extruded from the pipette by reaching in from the top. These two monolayers are moved toward each other by appropriate mechanical procedures and, at the place of contact, form a true bilayer.

established whether the bilayer did contain protein. The method is a very interesting one, because it offers the hope of constructing bilayers containing *different proteins* in the two monolayers.

Finally, I wish to mention a procedure invented by Träuble and Grell (1970) in Eigen's laboratory (Figure 4). Here, too, the bilayers are formed stepwise. In the first step, an emulsion of water droplets is formed in a bulk phase of benzene to which a small amount of phosphatidyl choline has been added. The emulsion is formed by intense ultrasonic irradiation. The droplets are of fairly uniform size, about 400 Å in diameter, and are coated with a monolayer of the phospholipid. This emulsion is then layered on top of a different aqueous phase. Some more phospholipid is added to the benzene to form an interfacial layer between the bulk aqueous phase and the benzene, and the droplets of the emulsion (the prevesicles) are forced from the benzene phase into the water phase by high-speed centrifugation. In their passage through the interface, the prevesicles cover themselves with a second layer of phospholipid and now constitute vesicles surrounded by a true lipid bilayer. Here the possibility exists of making the bilayer asymmetric, with respect to the polar lipid, and making the inside aqueous phase different from the outside one. Moreover, that these vesicles can be prepared with a total surface area per milliliter vastly exceeding that obtainable by any other method opens the way to a great number of physical studies not accessible with the other procedures. Vesicles of phospholipids can also be formed in a single step, by sonication of a suspension of lipid in water (Huang, 1969).

FIGURE 4 Production of masses of microvesicles by a twostep procedure (Träuble and Grell, 1970). Step 1. Formation of a water emulsion in a benzene phase containing small amounts of phospholipid. Prevesicles are formed on intense sonication. Step 2. Another aqueous phase is overlaid with

the emulsion, and an interfacial monolayer of phospholipid is formed. Step 3. The prevesicles of the emulsion are forced through the interfacial monolayer (high-speed centrifugation). Vesicles bounded by a lipid bilayer are formed.

Let us return to the flat bilayers introduced by Mueller and Rudin. These are reasonably permeable to substances soluble in both water and lipid. One of these substances is water itself, whose solubility in hydrocarbon solvents is actually surprisingly high, around 10^{-3} molar. The nature of water dissolved in hydrocarbon has not been studied by modern methods. It is not known to what extent it is aggregated and, if it is, in what kinds of aggregates. Such a study would certainly be feasible and highly desirable.

These membranes are impermeable to substances of low solubility in hydrocarbon solvents or, more precisely, to substances for which the partition coefficient between water and the hydrocarbon phase is unfavorable for the latter. Foremost among these are anions and cations. As a result, the electrical conductance of such membranes is fantastically low, in most cases of the order of 10^{-8} mho cm⁻².

Läuger et al. (1967) made the interesting discovery that such membranes are relatively permeable to the iodide ion and much more so in the presence of the $I_{\rm 2}$ molecule. Probably this case is also a simple one of partitioning between water and lipid; the larger the volume over which the charge of the ion is distributed, the less energy is needed to transfer such an ion from its aqueous environment with a dielectric constant around 80 to the lipid phase with a dielectric constant around 2. The iodine molecule enhances the partition of the iodide ion in favor of the lipid phase. The mechanism of this enhancement has not yet been clarified unambiguously. It is possible that I_3^- or I_5^- ions are formed, thus spreading the charge over a larger volume and reducing the electrostatic energy needed for transfer to the lipid phase (Finkelstein and Cass, 1968). However, more indirect effects of I2 on the lipid phase also can be conceived.

The unmodified lipid bilayer membrane imitates the thickness, electric capacitance ($\sim l\mu f \text{ cm}^{-2}$), and the water permeability of real membranes. It fails in its electrical conductance in not being constrained to constant thickness when torn, and in all higher functions.

PROTON CARRIERS Next in sophistication we may consider the remarkable effects of *uncouplers*, i.e., substances that, in mitochondria, uncouple oxidation from phosphorylation. Dinitrophenol is the classic example, and related compounds have been introduced recently. When such compounds are added to mitochondria, the electron transport system of respiration continues to operate at a high rate, but the energy supplied by this transport is not used for the synthesis of ATP. The theories concerning the mechanism of this uncoupling naturally depend on our theoretical understanding of the coupling of oxidation and phosphorylation in the first place. One class of such theories derives from ideas of Peter Mitchell (1966; see also Lehninger, this volume). Mitchell noted that membranes, because they are invariably contour free, must necessarily divide space topologically into an inside and an outside. Thus, one can conceive of a biochemistry, situated in the membrane, which both creates and depends on the differences in the electrochemical potentials of solutes on the inside versus those on the outside. One can also conceive that the coupling between electron transport and phosphorylation might be mediated by such gradients. Specifically, Mitchell conceived that the electron transport creates a pH differential between inside and outside, and that the pH differential drives the synthesis of ATP. Uncoupling, from this point of view, would occur if the pH gradient fails to be established, for instance by making the membrane highly permeable to protons. It is still uncertain if this idea is correct with respect to the uncoupling of oxidative phosphorylation in mitochondria, but it has turned out that the uncouplers are indeed good proton carriers in lipid bilayers (Hopfer et al., 1968; Liberman and Topaly, 1968). At least that is what they seem to be at first sight. They increase the conductivity of the membrane in a manner that would be expected for a mechanism that allows both the neutral uncoupler and the anion to shuttle back and forth. The dependence of the conductance on the concentration of uncouplers and on the pH support the idea, but whether this is the whole story is still not clear. Certain experimental findings on the saturation of this mechanism point to complications. These have been pursued actively by L. J. Bruner (Bruner, 1970).

DEVIATION FROM OHMIC BEHAVIOR A striking feature of the conductance both of simple lipid bilayers and of those made more conductive by uncouplers is a symmetric nonlinearity in the I versus the V curve: with increasing applied voltage the current rises faster than proportionally to the voltage. The deviation from linearity becomes obvious around 30 mV and reaches a factor of about 5 near 100 mV. Läuger and his associates have made a thorough theoretical study of this nonlinearity (Walz et al., 1969; Neumcke and Läuger, 1969), and point out three possible causes, each of which is analogous to certain mechanisms well known in solid-state physics.

The first possible cause is referred to as "ion injection." When an insulating layer is interpolated between two layers containing a large number of mobile charge carriers, an applied voltage will effectively be limited to the insulating layer, caused by the accumulation of charge carriers of opposite sign at the two interfaces. Because of the interplay of thermal diffusion and electrical fields, however, the charge layers at the interfaces will not be infinitely thin. They will extend some distance into the conducting phases. The extent of this spread of the space charge and of the voltage is the greater the lower the carrier concentration. The net effect of this space-charge distribution is a dependence on the applied voltage of the concentration of the majority carrier at the lipid-water interface: the greater the applied voltage the higher the majority-carrier concentration and, therefore, the higher the ion injection. Walz et al. (1969) showed that for lipid bilayers this effect is appreciable only at ionic strengths of about 10^{-3} molar or lower, and that it should rapidly decrease with increasing ionic strength. Both these predictions are contrary to the actual findings, and therefore this cause cannot account for the bulk of the observed effect.

The second cause studied in detail (Neumcke and Läuger, 1969) considers the effects of the so-called image forces to which the ions in the lipid phase are subjected. These image forces are an expression of the polarization of the dielectric environments of the ions. The forces are situated very close to a lipid-water interface and lead to a strong attraction of any ion dissolved in the lipid phase toward the interface and thus to a lowering of its energy. In lipid bilayers, the effect of these forces is to increase the partition of the ions in favor of the lipid phase, and the increase is greater as the applied voltage is greater. In this case, quantitative analysis leads to results much closer to reality. One obtains an I curve versus a V curve, which is independent of the ionic strength and gives deviations from linearity of the right sign and the right order of magnitude, but they still are not quite large enough to account for the observations.

A third effect has, therefore, been considered and calculated in detail. This is the field dissociation effect first discovered by Wien many decades ago and accounted for quantitatively by Onsager in a classic paper (Onsager, 1934). Onsager showed that the applied field affects the association-dissociation equilibrium of dissolved salts, leading to a net increase in dissociation in the presence of high applied field strength and, therefore, in the number of charge carriers. The theory of Onsager has been modified (Neumcke et al., 1970) to the situation of thin bilayers and has been shown to account satisfactorily for the observed nonlinearity, when combined with the contribution of image forces mentioned above.

ION CARRIERS This nonlinearity does not seem to be present and is probably swamped out when lipid bilayers are modified by the addition of ion carriers, substances that increase the conductance of lipid bilayers still more than do the uncouplers. The history of this discovery is somewhat as follows. Among the vast number of antibiotics against bacteria discovered during the last decades are some that, when applied to mitochondria, lead to a strange accumulation of potassium ions. The mechanism of this K^+ accumulation is still controversial, but again the application of these agents to lipid bilayers has led to a beautifully simple result: the bilayers become highly permeable to K^+ and highly selectively so. Mueller and Rudin (1967b), who discovered this phenomenon, thought at first that these substances, which are ring molecules, accommodate the hydrated potassium ion in the center of the ring and were tailor-made to fit this hydrated ion. They conceived of these ring molecules as inserting themselves in the membrane-like washers, forming pores through which the ions might move. The truth turned out to be even more startling. When the first X-ray diffraction structure of one of these molecules (nonactin) came out (Kilbourn et al., 1967), it showed that the carrier wraps itself completely around the *naked* ion, suggesting that this complex could act as a "carrier pore" for shuttling particular ions across the membrane. A similar structure has recently been established for another K⁺ carrier, valinomycin (Pinkerton et al., 1969; Ivanov et al., 1969). Eigen, elsewhere in this volume, deals with the features that permit these molecules to carry out such a very specialized function.

HOLE PUNCHERS The next class of additives might be called "hole punchers." These are cyclic antibiotics containing a polyene chain as part of the molecule, but other portions of the ring are highly hydrophilic. Their effects on real membranes and on bilayers are contingent on the presence of cholesterol or some other sterol in the membrane. Nystatin and amphotericin B are the ones that have been studied most carefully (Finkelstein and Cass, 1968). These additives also increase the conductance of bilayers, but the effects that they produce are very different from those of ion carriers.

1. The additive must be present on both sides of the membrane to give reproducible results.

2. The conductance increase depends on a very high power of the drug concentration.

3. The conductance is based on an increased permeability to *anions* and is coupled with an increased permeability to water.

4. Anions are discriminated according to size.

5. The conductance has a very high negative temperature coefficient in contrast to that produced by the ion carriers. This permits the experimenter the neat trick of switching the conductance from one due to potassium to one due to anions by using bilayers to which both a K^+ carrier (valinomycin) and a hole puncher (nystatin) have been added. Simply by a change of a few degrees in temperature, the dominant conductance mechanism can be switched, and with it the membrane potential, if the solutions on the two sides are chosen appropriately.

GATEABLE ADDITIVES The last class of additives I wish to discuss are the gateable ones: EIM (excitation-inducing material, Mueller and Rudin, 1967a) and alamethicin (Mueller and Rudin, 1968). The first of these materials is a protein produced by a strain of *Enterobacter cloacae*; the second, a cyclic peptide containing 19 amino acids. Both substances are still very imperfectly characterized chemically. Both substances confer on lipid bilayers a conductance which varies over several orders of magnitude, depending on the applied voltage. Conductance is cationic but can be changed to anionic by the addition of such polycations as protamine, polylysine, or spermine. By playing with the applied voltage, salt gradients, or the polycationic additives, one can simulate many striking electrical phenomena characteristic of nerve-axon membranes, including resting potentials, action potentials, and rhythmic discharges. The molecular mechanisms here involved are still obscure. Especially, the basic question still unanswered is whether the sudden transitions from one state of conductivity to another bespeak a cooperative phenomenon on a large scale, such as a phase transition of the whole membrane, or a microcooperativity involving local conformational changes of oligomers. Perhaps the strongest argument in favor of the latter view comes from the observations of Bean et al. (1969), which showed that, on the addition of EIM, quantized increases in conductance can be seen, each quantum amounting to a conductance change of about 4 \times 10⁻¹⁰ mho. It seems plausible that these increases in conductance correspond to the opening of individual gates controlled by one or a few molecules of EIM. If such an interpretation is correct, then the excitations of the lipid bilayers produced with the help of these additives are not likely to be close relatives of true nerve excitations, because, for the latter, it seems probable to me that we are dealing with a true phase transition on a macroscopic scale (Adam, 1970).

NEW TECHNIQUES COMING OR HOPED FOR There is much need for more basic studies on lipid bilayers, naked or with additives. The lipids used should be chemically defined, as in the studies of the Läuger group; otherwise we cannot hope to obtain data interpretable in terms of specific mechanisms. Electrical measurements must be supplemented by other physical measurement, by the attachment of spin labels or fluorescent labels, or the development of technologies for absorption and reflection measurements adapted to these very thin layers.

A most promising approach is the study of the bulk phases of lipid-protein-water mixtures (Gulik-Krzywicky et al., 1969). Such mixtures give rise to a variety of phases which can be studied by X-ray diffraction techniques. The clarification of the structures possible in laminar phases, especially, should go a long way in helping us to assess the relative roles of lipid and protein in contributing to the basic structure of real membranes.

Another approach of great value for the understanding of the interaction of lipids and proteins in membranes is that pursued by Colacicco (1969). Here a monolayer of phospholipid is first formed at an air-water interphase. Various proteins are then introduced into the aqueous subphase, and the penetration of the protein into the monolayer is assessed by its effect on the surface pressure of the monolayer.

Perspective

It would seem that Nature, when she had invented the principle of membranes, found that she had caught on to a good thing, and proceeded to exploit this principle with the passion of the true inventor. As yet we have as little understanding of this general principle as we had of chromosomes, say, 30 years ago. Studies of physiologists, biochemists, and electron-microscopists have yielded some guidance in the characterization of special membranes, but the gap between this characterization and the light shed by the study of model membranes is still enormous.

Considering the relevance of the study of membranes to our over-all progress in biology and psychobiology, I do not think that we shall learn from such studies how any central nervous system functions or even be led directly to the solution of the great puzzles of neuroembryology. I do have a strong feeling, however, that radical progress in any of these fields will not come until the gap has been bridged that now exists between our understanding of the simplest model membranes and, say, the transducer membranes of sensory physiology. Here I am sure discoveries are still to be made that will rank with the greatest we have had in molecular biology.

61 Alkali-ion Carriers: Dynamics and Selectivity

MANFRED EIGEN and RUTHILD WINKLER

Alkali-ion carriers; concepts and facts

THE EXCITATION of the nerve membrane is intimately coupled to a fast exchange of sodium and potassium ions. Processes of this kind have been studied for a long time, and various mechanisms involving "pumps" and "carriers" have been proposed. Whatever those "demons" are, they must have a size-specific recognition site by which they distinguish selectively a given alkali ion from its (smaller and larger) homologues.

Actually, the hypothetical concept of the carrier reflects largely the difficulty in explaining selectivity in terms of simple ionic interactions. On the other hand, how the interaction of alkali ions with such carriers could be explained in chemical terms remained an unsolved problem as well.

Moore and Pressman (1964), Shemyakin et al. (1967), and Graven et al. (1966), have recently found that certain antibiotics bind potassium ions selectively and transport them through natural and artificial (lipid) membranes. Whether these antibiotics are, in fact, used as "carriers" has not yet been found out. Because they possess all the qualities once ascribed to a specific "carrier," however, we may well use them as model compounds in order to see how nature can account for such properties.

Table I contains a compilation of antibiotics which selectively either facilitate or interfere with specific alkali-ion transport through lipid membranes. The composition and spatial structure of these compounds have been studied in detail in various laboratories (for references, see Table I). Essentially, two groups of compounds can be distinguished.

1. Neutral macrocyclic compounds: All members of this group are cyclic molecules, and at neutral pH are uncharged (in the absence of the alkali ion). The carrier complex will therefore respond to an electric field via the charge of the alkali ion. The molecular weights are of medium magnitude, and the molecules are just large enough to surround the alkali ion with a hydrophobic coat. The composition varies widely. Thus, we find oligopeptides, such as gramicidin-S*; oligodepsipeptides (i.e., sequences of alternating amino acids and oxyacids), such as valinomycin and the

*The gramicidins A, B, and C are similar, but acyclic compounds.

enniatins; or other cyclic structures, e.g., simple polyethers or the macrotetrolides, which are discussed below in more detail. It is obvious that similar structures could be found also in protein molecules. Actually, some enzymes are known to bind sodium or potassium quite selectively. A feature of the above-mentioned cyclic compounds is that their molecular weights are considerably lower than those of even small protein molecules.

2. Charged open-chain compounds: These linear structures of various compositions all contain a carboxylic group. Thus, in the neutral pH range the uncomplexed molecules are negatively charged. The carboxylic group, however, is not necessarily involved in the coordinative binding with the metal ion. Rather, it is believed to form H-bonds to hydroxyl groups at the opposite end of the linear structure, thereby forming a cyclic conformation. The molecular weights are of a similar order of magnitude as those for the members of the first group.

All carriers possess a number of polar ligands, which are used to form a multidentate complex with the alkali ion. Large parts of the molecule, however, must be hydrophobic so that the carrier may easily penetrate into lipid membranes. As a consequence, the solubility in water is very poor. It will be seen that the particular architecture of the carrier is responsible for its unique functional properties.

It is quite obvious that a selective carrier action must be a consequence of a selective binding capacity for the different alkali ions. Thus, direct measurements of complex stability

constants by the use of different nonaqueous solvents, have been performed in several laboratories. Table II contains some examples. They generally confirm the above assumption, although the correlation between complex stability and membrane permeability is not always straightforward, indicating that other factors (kinetic properties, such as lifetime, loading rate, and so forth) are involved in the dynamics of ion transport across membranes. Nevertheless, the most striking result is the unique size dependence of the complex stability showing a pronounced maximum for a given ion, disfavoring larger as well as smaller sizes. This behavior is quite different from any size dependence due to simple electrostatic interaction.

Complexes of main group metal ions: stability and dynamics

Before starting a more detailed discussion of experimental data, we may ask for possible explanations for such a size specificity of complex stability. For alkali ions, specificity in binding is certainly not a consequence of a peculiar electron configuration, as it is for transition metal ions, such as Ni²⁺, Cu²⁺, and so forth. We are dealing here with ions of "noble gas"-like electron configuration, and we must therefore try to base our model on factors such as charge and size of the metal ion and peculiarities of structure of the complexing agent only.

The complex formation involves the substitution of one or several solvent molecules from the inner coordination sphere of the metal ion. If the incoming ligands can be arranged as freely as the solvent molecules (in the coordination shell), then-at least for a symmetrical, e.g., octahedral, arrangement-we should expect one of the two following monotonic size dependences:

1. The incoming ligand is more tightly bound than the solvent molecule to be substituted. The stability of the complex will decrease with increasing radius of the metal ion. The smaller the metal ion, the larger will be the gain in binding energy for each ligand.

2. The incoming ligand is less tightly bound than the solvent molecule. Here the size dependence of complex stability will be inversed, because the smallest metal ion will most strongly prefer the solvent molecules.

Such behavior is depicted in Figure 1. It is very important that in these cases-with decreasing metal-ion size-the cavity formed by the ligands can contract just as freely as does the solvent coordination shell. This may not always be possible, e.g., if the ligands are interconnected in a multi-

dentate chelate complex. Here the different ligands usually have some freedom of motion only as long as the cavity formed around the metal ion exceeds a certain size. Below this size the ligands may "freeze" into fixed positions, because steric hindrances, as well as ligand-ligand repulsion, will prevent further contraction of the cavity. Thus, the cavity will show an optimal fit for a metal ion of a certain size. For all metal ions larger than this critical size, the complex stability will increase with decreasing metal-ion radius, supposing that the ligands are more tightly bound than the solvent molecules. Below the critical size, however, this behavior is inversed, because there will be little or no gain in ligand-binding energy with decreasing metal-ion radius, and hence there will be no compensation for the increasing solvation energy. Note that this optimal fit will produce a maximum in the thermodynamic stability constant, but that this does not at all mean that the optimally fitted complex is the most stable complex in "absolute" terms.

The behavior described above is demonstrated in Figure 2. The lower curve describes the size dependence of the free

FIGURE 2 Free energy of solvation (lower curve) and chelation (upper curve for two hypothetical cases) as function of the reciprocal radius of alkali ions.

energy of solvation (r being the metal-ion radius). The upper curves represent two different size dependences for the free energy of ligand binding (including rest solvation). These curves are monotonic, i.e., the smallest ion shows the largest values, but, because the free energy of ligand binding bends sooner toward saturation (brought about by steric fixation of the ligands), the difference of the ligand binding and solvation curve may well show a maximum. Just such a difference determines the stability constant (K_{stab}) of the

metal complex. Note that the increase in free energy of ligand binding will be monotonic, regardless of whether Kstab increases or decreases. Note furthermore that the maximum of K_{stab} could be found at any position, depending on how soon the ligand-binding energy reaches saturation, but that this position does not necessarily coincide within the 1/r value at which saturation actually is reached. (The picture of optimal adaptation of a metal ion to the minimal size of the ligand cavity is oversimplified here in order to demonstrate the principle.) We may briefly summarize the main consequences of the above paragraph. A nonmonotonic size dependence, i.e., size specificity, is not a consequence of a special force, but is rather the result of the superposition of two influences-solvation and chelation. Both size dependences are monotonic per se but, owing to the special architecture of the complexing agent, level off with decreasing metalion size at different positions, so that the difference is no longer monotonic. If we remember that the solvation energies of Na⁺ and K⁺ differ by about 20 kcal/mole and that at room temperature 1.4 kcal/mole correspond to a difference of one order of magnitude in binding constants, we see easily that this "source" is sufficient to explain the observed binding specificities of carriers.

We now return to a discussion of experimental data. Some stability constants for various alkali-ion complexes are shown in Table II. A nonmonotonic size dependence as striking as it appears to be for some of these complexesactually has been observed in many other chelate complexes of main group metal ions. Some data for alkaline earth complexes are compiled in Table III. Note that the solvation energy for divalent ions is much larger than for monovalent ions, and thus differences (e.g., for Mg^{2+} and Ca^{2+}) may be much more pronounced. The above interpretation is also supported by the rates of complex formation, which appear to be much more uniform than complex stabilities. Table IV shows some rate constants of complex formation for Mg^{2+} and Ca^{2+} . The differences of the second-order rate constants within one group (e.g., Mg²⁺) are due mainly to differences in the charges of the complexing ligands, because the rates involve ion pair formation. If one accounts for this effect, i.e., if one relates the rate constant with the rate-limiting step of substitution of a water molecule from the inner coordination sphere of the metal ion, a quite uniform value of about 10^5 sec^{-1} for Mg²⁺ and 5 \times 10⁸ sec⁻¹ for Ca²⁺ is obtained throughout (Eigen and Wilkins, 1965).

Almost all this information about rates of ligand substitution in metal complexes has been collected during the last decade, after the introduction of modern techniques for the study of rapid reactions, such as nuclear magnetic resonance, electron paramagnetic resonance, and relaxation spectrometry (Eigen, 1963). A uniformity of complex formation rates, as shown with Mg²⁺ and Ca²⁺, was found for almost all metal ions studied so far. It is therefore possible to present

a condensed survey on characteristic rates. A more detailed discussion of such a "periodic table of rate constants" for metal ions in a given solvent (Figure 3) can be found elsewhere (Diebler et al., 1970). Here, we want to emphasize only two points:

1. Deviations from a monotonic size dependence are found only with the transition metal ions, in which special influences such as ligand field stabilization and Jahn-Teller effect are involved. On the other hand, main-group metal ions show a uniform behavior throughout. If the rate can be associated with an elementary step, it reflects the monotonic size dependence, as expected for simple electrostatic interactions.

2. Despite the high solvation energies, the substitution of a single solvent molecule (or ligand) from a "complete" solvation sphere appears to be rapid. For the alkali ions this substitution occurs within 10⁻⁹ seconds. This rate is found for any single ligand belonging to a "complete" solvation sphere before any further substitution occurs. The loss of solvation energy is compensated for by the ligand binding. It would be more difficult to remove a solvent molecule from an incomplete solvation sphere, i.e., without compensation for the loss of solvation energy.

The high speed of single-ligand substitution is important for an understanding of the dynamics of carrier action (see below).

688 ASPECTS OF MOLECULAR NEUROBIOLOGY

The study of alkali-ion complexes: solvents and indicators

The complexing mechanism of alkali-ion carriers have been studied in homogeneous solution. Methanol offers several advantages as a solvent.

1. Biological alkali-ion carriers are usually insoluble in water, owing to their lipophilic character, but are fairly soluble in methanol.

2. Because of the lower dielectric constant of methanol, complex stabilities, higher than those in water, are found, especially if charged ligands are involved. Thus, a more precise determination of stability and rate constants of otherwise quite weak complexes is possible.

3. The solvation of the cation in water and methanol is quite similar, as was shown by Strehlow (1952). There are only small changes of ΔG , ΔH , and ΔS if an alkali ion is transferred from water to methanol. The substitution behavior (mechanism and rate) might be quite similar for both solvents, so that studies in methanol can be considered representative for water as well.

4. Methanol can be used as a solvent for temperaturejump (T-jump) studies by both the Joule-heating and the microwave-heating methods. It even shows some advantages for field-effect and sound-absorption studies. As a consequence of the lower dielectric constant, the field effect for charged ligands is larger than in water. For uncharged ligands (e.g., the carriers described below under "The Na⁺⁻ Monactin Complex"), relatively large ΔH values are to be expected. Thus, the equilibrium will be very strongly temperature-dependent. Sound waves in methanol involve a pronounced temperature wave, which, in water of about room temperature, is nearly absent (owing to the density maximum at 4° C).

In order to observe the equilibration of alkali-ion complexes and to follow rapidly any change in equilibrium, it was necessary to find a suitable indicator for the alkali ions in methanol. No such indicator has been reported in the literature so far. However, Schwarzenbach and Gysling (1949) described murexide as a specific indicator for Ca^{2+} ions in aqueous solution.

Murexide is the ammonium salt of purpuric acid and has the following chemical structure:

The anion has a strong absorption maximum around $\lambda = 527 \text{ m}\mu$ ($\epsilon = 11700 \text{ in methanol}$), which is shifted on complexing with Ca²⁺ to shorter wave lengths. Most likely, complexing occurs between two of the oxygens next to the N-bridge.

The stability constant for the Ca complex in aqueous solution, as reported by Schwarzenbach, is not large (pK 2. 7). Mg^{2+} was found to form no complex to any appreciable extent, whereas Sr^{2+} and Ba^{2+} , according to Geier (1967), showed some tendency for complexing.

Although several other indicators have been reported in the literature as having much higher stability constants for the alkaline-earth ions, murexide seemed to be the best candidate for the indication of alkali ions in methanol for several reasons.

1. Murexide has a negative charge (distributed among the four oxygens next to the N-bridge), which is not protonated in the neutral pH range. Actually, the pK in aqueous solution is about zero and in methanol about 4 to 5. Alkali ions generally are quite weak in forming complexes, so it is very important that protons do not compete too strongly for the complexing site.

2. The spectral properties of murexide are peculiar. When complex formation occurs, the blue shift of the absorption maximum is probably due to some change in the orientation of the two rings relative to each other. Such an effect should be sensitive for weakly complexing ions, which otherwise would have only little influence on the electronic structure of the dye molecule. Figure 4 shows the spectral shift of the absorption maximum on titration with Na⁺. The well-defined isosbestic point indicates a simple complexing behavior. Those titrations were carried out for both the alkali and alkaline-earth series.

In the alkali series, the highest pK values were found for Na^+ in the alkaline-earth series corresponding to Ca^{2+} , as

FIGURE 4 Spectrophotometric titration of murexide with Na⁺. (25°C; $C_{Mur} = 4 \times 10^{-5} M$).

was to be expected from Schwarzenbach's results for aqueous solutions. Owing to the lower dielectric constant of the solvent, the stability constants in methanol are higher than in water by orders of magnitude, and show much more clearly the nonmonotonic size dependence as described in the preceding section of this paper. One may consider murexide as a "carrier" for Na⁺ and Ca²⁺. Here again, the maxima in the stability constants result from the balance between ligand binding and solvation energy, whereas the "absolute" stabilities of the complexes should parallel monotonically the sequences of ionic sizes. This is clearly indicated by the amount of wavelength shift and the increase in ϵ . Both λ_{max} and ϵ are largest for the smallest ion and decrease monotonically with increasing size, as seen in Figure 5.

FIGURE 5 Absorption curves for various alkali- and alkalineearth complexes with murexide.

For the alkali complexes, the stability constants can easily be determined from the titration curves (see Table V). Here K_{diss} is always much larger than the indicator concentration, and therefore can immediately be obtained from plots of $(E - E_0)/(E_{\infty} - E_0)$ versus $1/C_M$, in which the extinctions E, E_0 , and E_{∞} refer to the metal-ion concentrations C_M , 0, and ∞ (saturation), respectively.

A suitable indicator for studies of dynamic properties should have not only pronounced spectral shifts but also a sufficiently rapid performance. Only then can it be used for the observation of other complexing reactions. Actually, the indicator may still be used if it reacts with a speed comparable to that to be followed. In that case, however, one must know precisely the rate constants of the indicator for the evaluation of the relaxation spectrum of the coupled reaction system. Therefore, it was necessary to carry out rate measurements with the indicator-metal-ion system.

For all the alkali ions, these reactions turned out to be too fast to be resolved by the temperature-jump technique, the half times being below the microsecond range. An electricfield traveling wave technique with spectrophotometric observation-developed by Ilgenfritz (1966)- could, however, be used for these studies. In this technique the perturbation of equilibrium is brought about by a strong electric field utilizing the dissociation field effect. The method is applicable to any equilibrium between charged reaction partners. The present time-resolution of this method is 30 nanoseconds; thus the method is just suitable for detecting the relaxation effects for the reactions of Li⁺ and Na⁺ with murexide. Figure 6 shows a typical oscillogram. K+ (requiring a higher concentration because of its lower stability constant) was already beyond the resolution of this method. However, a lower limit for the rate constant could be derived; that constant almost coincides with the upper limit for a diffusion-controlled process. Even the measured value for Na⁺ is very close to this limiting value of about $2 \times 10^{10} \text{ m}^{-1} \text{ sec}^{-1}$. (For charged species, the rate constant of a diffusion-controlled recombination is somewhat higher in methanol than in water, as a result of the lower dielectric constant of methanol, which favors the electrostatic attraction of the reactants.) The present results suggest that the reactions for K+, Rb+, and Cs+ are diffusion controlled. The reaction of Na+ is almost diffusion controlled; only Li+ shows a somewhat lower value (see Table V).

We may conclude that, from both a static and a dynamic point of view, murexide appears to be an ideal indicator for alkali ions in methanol. The spectral shifts are characteristic and easily detectable. The stability constants are high enough and in a convenient range (most convenient for an investigation of biological carriers; see below). The rates are as high as they could be, i.e., they are diffusion controlled. Mu-

reaction. (For details, see Winkler, 1969.)

The Na+-monactin complex: structure and dynamics

Several carrier systems for alkali ions are described in the first section. We have chosen the macrotetrolide "monactin" as a model compound for a more detailed study of the equilibria and dynamics of complex formation.

Monactin belongs to a group of antibiotics that can be isolated from such microorganisms as actinomycetes. The chemical structure, as shown in Figure 7, was determined by Gerlach and Prelog (1963). X-ray analysis carried out by Kilbourn et al. (1967) indicates that the metal ion is sur-

 $\begin{array}{ll} R_1 = R_2 = R_3 = R_4 = CH_3 & \text{Nonactin} \\ R_1 = R_2 = R_3 = CH_3 & R_4 = C_2H_5 & \text{Monactin} \\ R_1 = R_3 = CH_3 & R_2 = R_4 = C_2H_5 & \text{Dinactin} \\ R_1 = CH_3 & R_2 = R_3 = R_4 = C_2H_5 & \text{Trinactin} \end{array}$

FIGURE 7 Chemical structure of macrotetrolides.

rounded by eight oxygens in a quasi-cubic arrangement, whereby the cyclic molecule is wrapped up like the seam of a tennis ball (see Figure 8A). All polar groups are "inside" the cyclic molecule, leaving a cavity for the metal ion that is optimally adapted to the size of K+ as reflected by the stability constants (see Table II). The values in Table II were determined by Pioda et al. (1967), using the technique of vapor-phase osmometry. As is seen, the Na⁺ complex of monactin is weaker than the K+ complex by more than two orders of magnitude, Li⁺ does not show detectable complex formation, and Rb+ and Cs+ complex measurably but more weakly than K⁺. The complex formation can be followed spectrophotometrically, with murexide used as indicator. Figure 9 shows the decrease of the Na⁺ murexide complex absorption on the addition of monactin. This method was used to follow the reaction behavior of monactin "instantaneously."

A few words may be added with regard to equilibrium measurements. Simon was the first to detect some equilibrium constants by using vapor-phase osmometry. With murexide as indicator, one may now also carry out spectrophotometric titrations. Moreover, temperature-jump measurements used for a study of the dynamics of equilibration also provide information on both equilibrium constants and enthalpies of reaction. Actually, this latter method has scarcely been used for equilibrium studies so far, but it turns out that it is more sensitive than most other methods known. The reason is that the T-jump amplitude (with spectrophotometric observation) is given by:

$$\delta \mathbf{E} = \frac{\partial \mathbf{E} \quad \Delta \mathbf{H} \ \delta \mathbf{T}}{\partial \ln \mathbf{K} \ \mathbf{R} \mathbf{T} \quad \mathbf{T}},$$

 δE being the change in extinction due to the T-jump δT , K the equilibrium constant, and ΔH the enthalpy of reaction.

In $\partial E/\partial \ln K$, all terms not containing lnK drop out so that this quantity is a unique function of K. For comparison,

FIGURE 8 Schematic representation of the spatial structure of alkali-ion macrotetrolide complexes, left. Molecular model of nonactin as compared with solvated K⁺ ion, above.

titration curves essentially yield $\partial E/\partial \ln C_M$, C_M being the concentration of the titration agent, such as the metal ions, but this quantity might become quite insensitive to lnK under certain conditions.

Another advantage of the relaxation amplitude method is that it yields direct information about the enthalpy of reaction. A special method has been worked out in which the

FIGURE 9 Decrease of Na⁺-murexide absorption upon addition of monactin (dotted line).

T-jump amplitudes of the metal-ion indicator are compared with the same system in the presence and absence of the carrier. The Δ H values obtained by this method are accurate by about ± 0.1 kcal/mole, although the total temperature variation may not amount to more than 3° C (Tjump). Such a small temperature variation, of course, is of great advantage in the study of biological systems. The method is described in detail elsewhere (Winkler, 1969). For monactin with sodium a Δ H value of -6.0 kcal/mole was obtained, indicating an appreciable entropy term of RlnK.

The equilibrium data obtained show clearly that specificity or selectivity is a property of the carrier molecule itself which is present as well in the absence of a membrane, i.e., in homogeneous solution. From the analysis of solvation energies and from the known structures, we also know how a carrier must be constructed in order to exhibit such a selectivity, but it is difficult to understand how such a system can be dynamically active in competing with any other type of transport.

Let us consider the carrier molecule as depicted in Figure 8B. The cavity is just large enough to accommodate the unsolvated metal ion. How does the metal ion get in? To strip off the whole solvation sphere would cost considerable activation energy and would slow the process. Thus, after we knew the architecture of the carrier molecule, an inescapable question was: How fast can such a carrier be loaded (and unloaded)? We knew from equilibrium studies that equilibration is complete within seconds. Thus, we tried first to measure the rates with the help of the temperaturejump technique. Because the sample cell represents the resistance of the discharge circuit, we could not reach very high time resolution. (Any cation concentration must be kept small so as not to interfere with the complex formation to be observed.)

Typical oscillograms are shown in Figure 10. The amplitude of the solution containing both the indicator and the carrier is more than twice as large as for the reference solution (containing only the indicator). That tells us that equilibration was complete within the time of resolution (i.e., about 1 millisecond). Actually, these very precise amplitude values (signal/noise > 10⁴) were used to determine K and Δ H of the carrier complex, as shown above.

A considerably higher time resolution can be reached by the electric-field pulse technique, which was used for the study of the metal indicator equilibrium. However, no field effect can be detected for the carrier complex, because monactin is a neutral molecule. On the other hand, enough heat is produced during the field pulse so that a (linear) shift of the extinction occurs, while the electric field is switched on (see Figure 11). Again, this shift was more than twice as large in the presence of the carrier, indicating that the equilibrium is established even within about 5 microseconds. The only method with sufficient time resolution, therefore, that could be tried was sound absorption. With the help of a resonance method recently developed by Eggers (1967/1968), a pronounced rise of absorption toward frequencies of some hundred kilocycles per second was indeed observed. This absorption curve was evaluated with the help of known equilibrium data and yielded the rate constant for the complex formation of Na⁺ with monactin.

The surprising fact is that this rate constant is as high as about $3 \times 10^8 \text{ m}^{-1} \text{ sec}^{-1}$. It is just one order of magnitude lower than the expected value for a diffusion-controlled recombination. (Note that monactin is a neutral molecule, so that the limiting value is considerably lower than for the negatively charged indicator ion.)

Alkali-ion carrier complexes: general behavior

How can such a process be envisaged? Apparently it is impossible for a completely or appreciably desolvated metal ion to slip into the carrier cavity. Removal of several solvent molecules in one step would cost too much free energy of activation. On the other hand, in the discussion of substitution rates we have seen that replacement of a single solvent molecule from an otherwise complete coordination sphere of any alkali ion can occur within 10^{-9} seconds. Thus, we must conclude that carrier-complex formation is a stepwise "redressing" process, in which every solvent molecule is substituted stepwise, so that a balance of solvation and

 $\Delta OD = 0.00072 / cm$

4 x 10⁻⁵ M murexide 1 x 10⁻³ M monactin 1 x 10⁻³ M Na ⁺ (6 x 10⁻⁴ M Na⁺) 4 x 10⁻⁵M murexide 6 x 10⁻⁴ M Na⁺

FIGURE 11 Amplitudes of field effect of Na⁺-murexide and monactin solutions. Due to heating by the electric field, the amplitudes shift linearly with time. As in Figure 10, this

shift is about twice as large for the solutions containing monactin. (Note also the constant shift due to temperature change after the field is switched off.)

ligand-binding energy is always maintained. We may write the mechanism as:

 $M_N + X_0 \rightleftharpoons M_N X_0 \rightleftharpoons M_{N-1} X_1 \rightleftharpoons \cdots M_1 X_{N-1} \rightleftharpoons M_0 X_N,$

in which the index in M denotes the number of solvent molecules in the coordination sphere of the metal ion and the index in X the number of ligands bound to the metal ion. Only the initial and final states are appreciably populated; thus we may consider the intermediates to be in a steady state. Then we obtain an expression for the over-all rate constant that tells us that the probability for the reaction to proceed at any intermediate position in either direction must be not far from 50 per cent and that the rate constants for the single steps of substitution are of the order of magnitude of 10^9 sec^{-1} , i.e., of the same order of magnitude as was found for the substitution of a single H₂O molecule from the coordination sphere of alkali ions in aqueous media (see Figure 3). If any of the steps of substitution were appreciably slower, the value of $3 \times 10^8 \text{ m}^{-1} \text{ sec}^{-1}$ for the over-all rate constant (which is only about one order of magnitude below the limiting value for diffusion control) could not be explained. In order to allow such a stepwise substitution, the carrier molecule must unfold the flexible "tennis-ball seam" to an almost annular conformation. This unfolding in the absence of the metal ion is favored by solvation of the polar groups inside the carrier molecule, which otherwise would repel one another considerably, and this solvation energy may balance the stress occurring in the "annular" conformation.

In conclusion, we may now formulate some rules for a design of an efficient metal-ion carrier:

1. The carrier molecule should possess electrophilic groups that can compete with the solvent molecules for metal-ion binding. These groups should be inside an otherwise lipophilic structure, which easily dissolves in membranes.

2. As many solvent molecules of the inner coordination sphere as possible should be replaced by the coordinating sites of the carrier molecule. For two ions of different size, the reference state may then involve as much as the total difference of free energy of solvation.

3. The ligand should form a cavity adapted to the size of the metal ion. "Optimal fit" is related to an arrangement in which the difference of the free energies of ligand binding and solvation is maximal. Often it almost coincides with "fittest" geometrical arrangement. Cavity formation involves ligand-ligand repulsion as well as steric fixation of the chelate.

4. The carrier molecule should possess sufficient flexibility to allow for a stepwise substitution of the solvent molecules. Otherwise, if complete or substantial desolvation were required for the ion to slip into the cavity, the activation barrier would be high and the reaction slow.

Rule 1 fulfills the biological requirement, i.e., to gate the ion through a (lipid) membrane. Rules 2 and 3 take care of a high selectivity, whereas Rule 4 allows fast loading and unloading of the carrier. Not many structures of low molecular weight are known that would allow a simultaneous observation of all four rules. Almost all the classical complexing agents are poor in one respect or another.

So far, this paper has not dealt with any biological process. Actually, the problem we have been concerned with looks more like a problem of inorganic chemistry than one of neurobiology. This is certainly true, but before we could find out about the mechanism of sodium-potassium exchange in the nerve membrane we had to replace the demons "carrier" and "pump" by well-understood molecular processes.

We see that nature has designed very special molecules that are both dynamically active and highly specific, two properties that often exclude each other. For instance, the rate constant of dissociation k_D is related to the binding constant by:

$$k_{\rm D} = \frac{k_{\rm R}}{K_{\rm stab}} \, . \label{eq:kdef}$$

If $k_{\rm R}$ reaches a limiting value (e.g., diffusion control), $k_{\rm D}$ decreases if $K_{\rm stab}$ increases. The rate constant $k_{\rm D}$ determines the rate of unloading. Thus, as long as the over-all process is determined by the transport rate, one may gain an advantage by increasing $K_{\rm stab}$, because this constant determines the specificity of binding. If, however, the rate of unloading becomes so slow that it determines the over-all rate, all further gain in specificity is lost by slowing down the unloading ing rate.

For K⁺ and monactin, K_{stab} is 2.5 × 10⁵ M⁻¹. Thus, in order to keep k_D above 10³ sec⁻¹ (millisecond range), k_R had to be as high as 2.5 × 10⁸ M⁻¹ sec⁻¹. Such a K⁺ carrier would then be optimally adapted to the millisecond time range. The molecule solves the problem of quick loading by a conformation change, i.e., from an annular to a spherelike

conformation—a principle that is used in a similar way by protein molecules.

Problems to be solved

We may now proceed to try to solve the problems that are more closely associated with a biological system. As a next step, we must answer the following questions:

1. How fast is the rate of loading and unloading if the carrier is sitting in the membrane and the whole process takes place in the interface?

2. What is the rate-limiting step of transport in artificial and natural membranes?

3. What are the carriers used for alkali-ion transport in nerve membranes?

4. How can the mechanism be switched on and off by an electric field and how is it coupled to a pump-facilitating active transport?

To answer the first and second questions, measurements with artificial and natural membranes are required. Relaxation spectrometry would be the adequate method to find out about the rate-limiting step, because the relaxation spectrum contains the time constants of all detectable intermediate steps involved in the over-all mechanism. For those studies, small membrane vesicles would be required. Max Delbrück (this volume) mentioned the various methods for the preparation of those vesicles. Actually, the work of Huang (1969), as well as that of H. Träuble and E. Grell (private communication), was started for this purpose. Relaxation studies on single bilayers using optical techniques with high time resolution may be considerably more difficult. On the other hand, the vesicles should also include protein-lipid systems.

The third question, of course, is a key question. The carriers studied here are antibiotics; it is not known whether they transport alkali ions in bacterial and, possibly, in mammalian membranes. Studies with Tl^+ ions (which have been found to replace specifically K⁺ and Rb⁺ in certain enzymes [Kayne, private communication]) are being carried out by Müldner to answer this important question.

The fourth question finally will bring us closer to processes related to the nerve membrane. The answer to it (and the corresponding model studies) will depend on the nature of the carrier. The carrier may be a small molecule like the antibiotics discussed in this paper. Such a molecule could be linked with an "allosteric" protein involved in the pump mechanism. The transport may just as well be facilitated by a membrane protein directly, or by a special membrane structure. In all these cases, specificity will depend on similar factors, as discussed in this paper (a balance of solvation and ligand binding by either of the mentioned structures), but the switching mechanism may be quite different for the various models. Note: For a more detailed description of experiments and methods, see Winkler (1969). The aspect of metal complexing is treated in more detail in Eigen (1963) and Diebler et al. (1970). The broad subject of specific ion carriers was reported in an NRP work session (Eigen and De Maeyer, in press).

62 Molecular Motion in Biological Membranes

HARDEN M. MC CONNELL

BIOLOGICAL MEMBRANES offer many unsolved and challenging problems in biochemistry and structural chemistry. Our present discussion is concerned with *molecular motion* in membranes. We first describe in some quantitative detail the motion of a selected number of paramagnetic probes ("spin labels") in various biological membranes. Our analysis of the resonance spectra leads us to the conclusion that some membranes contain highly fluid hydrophobic regions, doubtless arising from the flexible hydrocarbon chains of the lipids. We then discuss the molecular basis of membrane fluidity. Finally, we speculate on the biological functions of membrane fluidity, particularly in relation to transport through membranes.

Motions of spin-labels in membranes

During the past two years W. Hubbell, A. Horwitz, R. Kornberg, and I have undertaken a study of membranes using spin labels.

It will be recalled that a spin label is a synthetic organic free radical that can be incorporated in a biological system in order to yield kinetic and structural information through the paramagnetic resonance spectrum (Hamilton and Mc-Connell, 1968; Griffith and Waggoner, 1969). Significant kinetic and structural information can also be obtained from the nuclear resonance spectra of biochemical systems containing spin labels (Weiner, 1969; Mildvan and Weiner, 1969a, 1969b). The technique has a number of interesting features. For example, the paramagnetic resonance signals are essentially free from interference, because an extremely small proportion of the molecules in a biological system is paramagnetic, and only a small fraction of these gives detectable resonance signals under physiological conditions. On the other hand, the spin-label molecule or group always represents some perturbation on the system under study, and the significance of the structural and biochemical actions of the labeling molecules must always be carefully assessed.

The spin labels we have used in our work are nitroxide free radicals having the general formula

HARDEN M. MC CONNELL Stauffer Laboratory for Physical Chemistry, Stanford, California

In this formula, R is usually designed so that the label is directed to some particular site or group of sites in a biological macromolecule. When the label is bound to a biological system so that it has a fixed orientation in space (static case), information on this orientation can be obtained from the resonance spectrum (McConnell, 1967; Hamilton and Mc-Connell, 1968). When the molecule is tumbling, isotropically or anisotropically, information on this motion can be obtained when the correlation times are in the range of 10^{-7} to 10^{-9} seconds (Stone et al., 1965; Hubbell and McConnell, 1969a, 1969b). Finally, under favorable conditions, the resonance spectra in biological systems are sensitive to the polar or hydrophobic character of the environment (Hubbell and McConnell, 1968).

One of our earliest and most striking results was the observation that certain (intact) membranes contain hydrophobic regions of high fluidity (low viscosity) (Hubbell and McConnell, 1968). Figure 1 shows the paramagnetic resonance of the spin-label 2, 2, 6, 6-tetramethylpiperidine-1oxyl (TEMPO) that has been added to a Ringer's solution containing an active vagus-nerve fiber of the rabbit.

FIGURE 1 Paramagnetic resonance spectrum of the spin label TEMPO in the fluid hydrophobic region of the rabbit vagusnerve fiber (A) and in the surrounding aqueous solution (B).

In Figure 1, signal A arises from TEMPO dissolved in a liquid-like hydrophobic region of the nerve fiber, and signal B arises from TEMPO dissolved in the surrounding aqueous solution. The widths of the individual lines are of the same order of magnitude (\sim 2 gauss), showing that in both cases TEMPO is tumbling very rapidly and nearly isotropically, with a correlation time of the order of magnitude 10⁻⁹ seconds. Essentially the same spectrum has been seen for TEMPO in the presence of the walking-leg nerve fiber of the Maine lobster, *Homarus americanus* (Hubbell and Mc-Connell, 1968).

In order to study further the hydrophobic regions of membranes, Hubbell has prepared a number of other spin labels, including the following molecules (Hubbell and Mc-Connell, 1969a, 1969b):

Spin label II is the N-oxyl-4', 4'-dimethyloxazolidine derivative of 5α -androstan-3-one- 17β -ol, and spin labels III (m, n) are the N-oxyl-4', 4'-dimethyloxazolidine derivatives of the n + 2 keto acids having m + n + 3 carbon atoms. Models of spin labels I, II, and III (12, 3) and III (5, 10) are shown in Figures 2, 3, and 4. (Label III [5, 10] was first used by Keith et al. (1968) for biosynthetic incorporation into phospholipids of *Neurospora crassa*.)

Amphiphilic labels of types II and III (m, n) are particularly useful for studying membranes, because they bind to a great variety of membranes, their resonance spectra are often easily analyzed, and in favorable cases their orientation relative to membrane surfaces can be determined from the anisotropy of the resonance spectra. As examples, Figures 5 and 6 show the resonance spectra of amphiphilic labels in the nerve-fiber membranes, and in erythrocytes (oriented by hydrodynamic shear) as a function of the orientation of the anisotropic membrane distribution relative to the applied magnetic field. In the case of the erythrocytes, the preferred orientation of the long amphiphilic axis is parallel to the cylinder axis of the erythrocyte, and, in the case of the nerve fiber, the preferred orientation of the long amphiphilic axis is perpendicular to the direction of the common axonal cylinder axis (Hubbell and McConnell, 1969b). In the case of the steroid label II, the long amphiphilic axis is **u**. For labels III (12, 3) and III (17, 3), the preferred conformation of the label in the membranes is evidently one in which the oxazolidine ring is parallel to the local membrane surface.

FIGURE 2 Pauling-Corey-Koltun model of spin label I, 2, 2, 6, 6-tetramethylpiperidine-1-oxyl (TEMPO). Note the *approximately* spherical shape of the molecule.

The motions of labels II and III (12, 3), III (17, 3), and III (5, 10) in various membranes are particularly interesting. In brief, these motions are deduced from the observed paramagnetic resonance spectra, as follows. In the absence of any motion, the paramagnetic resonance of the nitroxide group in a spin label can be represented by the spin Hamiltonian, 3C.

$$\mathcal{K} = |\beta| \mathbf{S} \cdot \mathbf{g} \cdot \mathbf{H}_{o} + \mathbf{h} \mathbf{S} \cdot \mathbf{T}' \cdot \mathbf{I} - \mathbf{g}_{N} \beta_{N} \mathbf{I} \cdot \mathbf{H}_{o} \,. \tag{1}$$

In equation (1), **S** and **I** represent the odd-electron and N¹⁴ spin angular momentum operators, and **g** and **T** are the g-factor and nuclear hyperfine tensors. β and β_N are the electron and nuclear Bohr magnetons, h is Planck's constant, and \mathbf{H}_0 is the applied field vector. In the presence of molecular motion, this Hamiltonian becomes effectively time-dependent, because the tensors **g** and **T** are molecule fixed, and the field vector \mathbf{H}_0 is laboratory fixed. Under suitable conditions the solution of the Schrodinger equation, or density matrix equation,

$$\operatorname{ih} \frac{\partial}{\partial t} \rho = \Im c \rho - \rho \Im c$$
, (2)

leads to an effective or average Hamiltonian, \mathcal{K}' ,

$$\mathfrak{K}' = |\beta| \mathbf{S} \cdot \mathbf{g}' \cdot \mathbf{H}_{o} + \mathbf{h} \mathbf{S} \cdot \mathbf{T}' \cdot \mathbf{I} - \mathbf{g}_{N} \beta_{N} \mathbf{I} \cdot \mathbf{H}_{o}, \quad (3)$$

of which the tensors \mathbf{g}' and \mathbf{T}' are suitable averages of the elements of \mathbf{g} and \mathbf{T} (Hubbell and McConnell, 1969a, 1969b). The paramagnetic resonance spectra of II and III (12, 3) and III (17, 3) in the nerve-fiber membrane can be accounted for by an anisotropic rotational diffusion of these molecules about their long amphiphilic axes. This means that the rotational frequencies are large compared with the corresponding anisotropies in the spin Hamiltonian, that is, large compared with frequencies in the range of 10^7 to 10^8 seconds⁻¹. In our experimental studies, the elements for \mathbf{g}

FIGURE 4 Pauling-Corey-Koltun models of the spin labels I (12, 3) (left) and I (5, 10) (right). These are the N-oxyl-4', 4'-dimethyl-oxazolidine derivatives of 5-ketostearic acid and 12-ketostearic acid, respectively.

FIGURE 5 Paramagnetic resonance of the N-oxyl-4', 4'-dimethyloxazolidine derivative of sodium 5-ketotricosanoate (spin label I [17, 3]) in the walking-leg nerve fiber of *Homarus americanus*. (a) minced nerve; (b) applied field perpendicular to cylinder axis of nerve fiber; (c) applied field parallel to cylinder axis of nerve fiber. The g-factor for the center of the outer (inner) hyperfine extrema is 2.0031 \pm 0.001 (2.0064 \pm 0.001).

FIGURE 6 Paramagnetic resonance of the N-oxyl-4', 4'-dimethyloxazolidine derivatives of (a) $5-\alpha$ -androstan-3-one- $17-\beta$ -ol (spin label II) and (b) sodium 12-ketostearate (spin label I [5, 10]) in erythrocytes oriented by hydrodynamic shear, with the applied field perpendicular and parallel to the shear plane. For II, the center point g-factor is close to the isotropic value for both orientations, 2.0057. For I (5, 10) the outer (inner) hyperfine extrema center at $g = 2.0027 \pm 0.001 (2.0057 \pm 0.001)$. The sharp signals at the isotropic splitting are due to I (5, 10) in solution in equilibrium with the bound label.

FIGURE 7 Paramagnetic resonance of the N-oxyl-4', 4'-dimethyloxazolidine derivative of sodium 5-ketotricosanoate (spin label I [17, 3]) in a sonicated dispersion of purified soybean phosphatides, pH 8.0.

and \mathbf{T} are determined from an analysis of the resonance spectra of spin labels in single crystals of a suitable host, and the elements of \mathbf{g}' and \mathbf{T}' are deduced from the spectra of the labels in the membrane of interest.

As a specific example, the paramagnetic resonance of III (17, 3) in sonicated lipid dispersions is shown in Figure 7. The quantitative analysis of this spectrum shows that the oxazolidine ring undergoes a rapid anisotropic rotational motion (probably around the long amphiphilic axis of the molecule) and that the root mean square angular deviation of the oxazolidine ring from its average orientation is $\sim 26^{\circ}$. The resonance spectrum of III (17, 3) in the nerve fiber is very similar, but the anisotropic rotational motion is clearly slightly slower, and the corresponding mean angular deviation is 24°. The corresponding angular deviations are 16° in erythrocytes and 0° when III (17, 3) is bound to bovine serum albumin.

Although the resonance spectra of III (17, 3) and III (12, 3) are similar to one another in the sonicated lipid and nervefiber membranes, the spectra of III (5, 10) are remarkably different. Here the nitroxide group shows rapid and effectively isotropic motion. Thus, the polar head-group regions of the sonicated lipid dispersions and nerve-fiber membranes are relatively rigid; the hydrocarbon tail region is correspondingly more fluid.

As mentioned earlier, label II takes up a preferred orientation in membranes, with the long amphiphilic axis doubtless perpendicular to the local membrane surface. An analysis of the spectrum of II also shows a rapid anisotropic motion around the long amphiphilic axis \boldsymbol{y} , this time with a large frequency compared to 10^8 seconds⁻¹.

The anisotropic motions of labels II, III(17, 3), and III (12, 3) are associated with the facts that the nerve membrane binding sites are fluid, and one end of these molecules is "anchored" at a polar surface. What would happen to the motion of II if the 17-OH group were suddenly removed? We have found that the corresponding label, the N-oxyl-4', 4'-dimethyloxazolidine derivative of 5α -androstan-3-one, undergoes rapid and effectively isotropic motion in the nerve-fiber membrane. This result certainly supports the plausibility of models of perpendicular transport involving the rotations of relatively rigid proteins in the fluid hydrophobic region. Note that the time required for rotation for the rigid steroid molecule (without the OH group) is $\sim 10^{-8}$ seconds, even though the molecular weight is relatively large (\sim 376). If we make the reasonable assumption that the correlation time for rotation is roughly proportional to molecular weight, a protein of molecular weight 37, 600 could still undergo a rotation in $\sim 10^{-6}$ seconds, if substrate binding produced a conformation change resulting in a disappearance of all exposed polar groups on the surface of the protein.

In our exploratory studies of membranes using spin labels, we have used labels I, II, and III (m, n) to study many different types of membranes (nerve fibers, myelin, bacteria, mycoplasma, synaptosomes, the sarcoplasmic system of muscle, erythrocytes, mitochondria, and *Nitella*). Unfortunately, these experiments are far from complete. Not all the above labels have been used with each membrane, quantitative binding studies have not been carried out, and many more labels must be synthesized and tested. Even so, we shall attempt to make some preliminary generalizations from our results.

The sarcoplasmic system of rabbit muscle shows the highest fluidity of any membrane we have yet examined. It is possible to isolate closed membrane vesicles from rabbit muscle which actively accumulate calcium ion in the presence of adenosine triphosphate (ATP) (Hasselbach, 1964; Martonosi, 1968). These vesicles show this high fluidity. The study has been carried out in this laboratory by R. Kornberg and W. Hubbell. The same degree of fluidity in these membranes is observed in the intact muscle system (Hubbell and McConnell, 1968).

A relatively high degree of fluidity has also been observed in the rabbit vagus-nerve fiber and in the walking-leg nerve fiber of the Maine lobster. We think it likely that the high fluidity of these nerve-fiber membranes is due to the axolemma, rather than to the surrounding Schwann cells. Thus, the axolemma in the squid axon is more strongly perturbed by low concentrations of detergents than is the surrounding Schwann cell membrane (Villegas and Villegas, 1968), which would be expected if the axolemma were the more fluid. Also, the relatively low proportion of myelin in the rabbit vagus is not expected to contribute significantly to the observed fluidity in the vagus-nerve fiber, because preliminary experiments indicate that myelin is not highly fluid (Hubbell and McConnell, unpublished). Other than myelin, membranes of relatively high viscosity include the membranes of erythrocytes, mitochondria, and *E. coli*. The limiting membrane of the *Halobacterium* is the most rigid of any lipid-containing membrane we have yet examined (McConnell, Hubbell, and Stoeckenius, unpublished).

What is the molecular structure of the highly fluid regions we have detected in the neural and sarcoplasmic membranes? The spin-label spectra indicate very strongly that it must be a lipid bilayer. Our first reason for this assertion is the similarity between the resonance spectra of labels I, II, III (17, 3) and III (5, 10) in the nerve fiber and in sonicated phospholipid dispersions. For example, the resonance spectrum of III (17, 3) in sonicated phospholipids is shown in Figure 7, and may be compared with the resonance spectrum of this label in the nerve fiber as seen in Figure 5. Also, the spectral change observed in going from label III (12, 3) to label III (5, 10) is quite similar in both the nerve fiber and in sonicated phospholipids, and this change demonstrates the high fluidity of the hydrocarbon tail region relative to the polar head-group region. Our second reason for believing that these labels bind to fluid bilayers is the observed preferred orientation of the amphiphilic labels, which is perpendicular to the membrane surface.

In concluding this section on the motion of spin labels in membranes, it should be noted that other investigators have used other physical techniques to study membranes and phospholipid suspensions. Studies particularly relevant to the question of molecular motion in the hydrophobic regions of membranes have been summarized by Luzzati (1968), Chapman (1968), and Branton (1969). Insofar as there is direct overlap, our spin-label results are in excellent accord with these other studies. We think, however, that the spin-label spectra provide the most *direct* evidence for molecular *motion* in the hydrophobic regions of *intact* membranes.

Molecular origin of membrane fluidity

The fluid hydrophobic regions revealed by the above spinlabel studies are doubtless associated with the long hydrocarbon chains of the membrane lipids. It is well known that long-chain fatty acids as well as diacylphosphatides show one or more endothermic phase transitions associated with a stepwise melting of the hydrocarbon chains. An excellent review has been given by Chapman (1968). This investigator has shown by nuclear resonance studies that the hydrocarbon chains of certain pure lipids (e.g., 1, 2-dimyristoylphosphatidylethanolamine) show gradually increasing motion with increasing temperature until the chains "melt" at the temperature of a marked endothermic phase transition.

In phospholipids (e.g., diacylglycerolphosphatides) as well as in the fatty acids themselves, the endothermic transition temperatures are reduced when the fatty-acid chains are shortened, or when one or more carbon-carbon double bonds are introduced into the chains, or both. The introduction of *cis* double bonds lowers the transition temperatures more than does the introduction of trans double bonds, but the chains containing trans double bonds do melt at temperatures below those of the corresponding saturated chains. The literature on this subject has been reviewed by Chapman (1968). Here we only summarize briefly what we believe are the crucial structural principles involved in determining the melting points, and fluidities, of hydrocarbon chains.

In comparing different hydrocarbon chains, we assume them to be in a completely hydrophobic environment, and so neglect possible second-order interactions between the hydrocarbon chains and polar groups, or molecules, or both.

The preferred low-temperature conformation of a saturated hydrocarbon is extended, all trans, as shown in Figure 8 for octadecanoic acid, C17H35 (COOH). Salem (1962) has shown that the van der Waals dispersion interaction between extended (all trans) saturated hydrocarbon chains is of the form

$$W_{disp} = A \frac{3\pi}{8\ell} \frac{N}{D^5}$$

in which $\ell = 1.26$ Å (the projection of the carbon-carbon vector along the chain direction), D is the perpendicular distance between the chains, N is the number of CH₂ groups in the chains, and A is a constant (-1340 kcal/Å⁶ mole). At a typical distance of 5 Å, this formula yields an interaction energy of 0.4 kcal/mole per CH2 group. Two stearic acid molecules (N = 18) at a separation of 4.8 Å interact with an attractive dispersion energy of -8.4 kcal/mole. The strong dependence of the attractive intermolecular dispersion energy on intermolecular distance signifies that any modification of the chains that reduces the closeness of packing should increase the fluidity of the hydrocarbon chains, or reduce their melting points if they are not already fluid.

Unsaturated fatty-acid chains in bacterial and mammalian phospholipids have *cis* carbon-carbon double bonds. A model of the unsaturated cis fatty acid, 9-octadecenoic acid, is shown in Figure 8, in a lowest-energy conformation (see Flory, 1969). It is clear that the "kink" in the chain must reduce the closeness with which such hydrocarbon chains can be packed one against the other. This should be particularly significant in the usual situation in which the lipids contain mixtures of fatty acids differing in the degree of unsaturation.

The introduction of a trans carbon-carbon double bond into a saturated fatty-acid chain also produces a kink in an otherwise straight hydrocarbon chain. Figure 8 shows a model of one low-energy conformation of 9-octadecenoic acid with a trans carbon-carbon double bond between carbon atoms 9 and 10. Here, again, we expect a reduction in the ease with which hydrocarbon chains can be packed one

FIGURE 8 Pauling-Corey-Koltun models of lowest energy conformation sof (left), all trans octadecanoic acid; (center), trans-9-octadecenoic acid; and (right), cis-9-octadecenoic acid.

against the other, especially in typical lipid systems in which a mixture of saturated and various unsaturated chains is present.

The presence of carbon-carbon double bonds in fattyacid chains must also play another significant role in contributing to the fluidity of the hydrophobic regions. That is, in highly fluid regions of membranes it is clear that the long hydrocarbon chains must be flexing and twisting so as to require internal rotations around the carbon-carbon single bonds. The introduction of carbon-carbon double bonds *reduces* the barriers to internal rotation for adjacent carbon-carbon single bonds. Thus, in the following sequence of carbon-carbon bonds,

the barrier to rotation about the b-c single bond is of the order of 3 kcal/mole, when a-b is a single bond (Flory, 1969). On the other hand, when carbon atoms a and b are joined together by a double bond,

the barrier to internal rotation about the b-c single bond is only 2 kcal/mole (Flory, 1969).

Thus, the introduction of carbon-carbon double bonds into long hydrocarbon chains enhances fluidity by two distinct mechanisms: (1) the double bonds introduce "kinks" that decrease the efficiency of close molecular packing of the hydrocarbon chains; and (2) the double bonds *facilitate* internal rotations around adjacent carbon-carbon single bonds.

We may now consider factors that can be expected to reduce the molecular fluidity of the hydrocarbon chains in a bilayer structure, for a fixed hydrocarbon chain composition. It is known from both nuclear resonance and spinlabel studies that the fluidity of phospholipid dispersions is reduced by the incorporation of cholesterol (Chapman, 1968; Hubbell and McConnell, 1968). We interpret this as signifying no highly specific interactions between the fattyacid hydrocarbon chains and the cholesterol molecule, but rather the fact that the cholesterol molecule itself has a rigid structure that inhibits the bending motions of neighboring hydrocarbon chains. If this interpretation is correct, then the introduction of any relatively large and rigid hydrophobic structure into an otherwise highly fluid chain region should reduce the molecular motion. (The effect of the antibiotic gramicidin S on phospholipid fluidity has been noted by Hubbell and McConnell [1968].) On the other hand, the introduction of cholesterol into an otherwise relatively rigid hydrocarbon chain region (say, straight-chain saturated hydrocarbons) may very well increase the molecular motion (Chapman, 1968).

If we make the very reasonable assumption that proteins "inside" the hydrophobic region of membranes have hydrophobic exteriors, and are just as "rigid" as are the watersoluble proteins familiar to us from X-ray diffraction studies, we may conclude that such proteins will tend to reduce the fluidity of an otherwise fluid ensemble of lipids. The great differences we have seen in the fluidity of different membrane systems may be due in part to this effect of proteins with hydrophobic surfaces.

Biological role of membrane fluidity

The high membrane fluidity we have observed in our experiments is in sharp contrast to the relatively rigid structures that are so familiar to us from X-ray studies of crystalline proteins and nucleic acids. Indeed, this high hydrophobic fluidity is so unique relative to other assemblages of biological macromolecules that one may assume that this fluidity has a special function in biological processes. Of course the hydrophobic character of the fluid region provides a permeability barrier for water-soluble substances. Certainly pure protein membranes could likewise provide excellent permeability barriers, judged from the (lipid-free) protein gas vacuole membrane of Halobacterium. Thus, a significant role of lipids in membranes must be to provide a fluid permeability barrier. Regions of membranes having (protein)-(lipid bilayer)-(protein) structures may have both rigid protein and fluid lipid permeability barriers.

A fluid permeability barrier must have special biological functions. For example, it surely offers a self-sealing capacity in the event a membrane is injured, as well as a degree of flexibility in the biosynthetic self-assembly of the membrane. Of perhaps even greater interest is the likelihood that this fluidity permits transport both perpendicular and parallel to the membrane surface. We shall not attempt to discuss parallel transport, except to mention that it may well be involved in lipid movement from the synthetic point of origin to the membrane target site. (The insect sex attractant bombykol [Schnieder and Kaissling, 1956; Butenandt and Hecker, 1961] may also move parallel to the surfaces of membrane-like structures [Adam and Delbrück, 1968].)

We suggest that a crucial role of membrane fluidity in connection with perpendicular transport is the maintenance of a permeability barrier near proteins that are "moving" in the hydrophobic region, to provide transport of ions, or
molecules, or both through the membrane. For example, consider the (facilitated) transport of the polar, water-soluble molecule lactose,

through a membrane with a typical thickness of the order of 100 Å (e.g., the limiting membrane of E. coli). This large polar molecule must be in contact with polar groups as it moves from one side of the membrane to the other; the polar environment is doubtless provided by stereospecific binding site (or sites) on one or more membrane proteins. Thus, not only does a large molecule traverse the membrane, but an even larger protein binding site moves through the membrane. The protein itself is certainly not fluid, so a very large rigid structure must move from one side of the membrane to the other, without great frictional resistance, and without opening up to other water-soluble ions and molecules, holes, cracks, or other breaks in the permeability barrier. These conditions surely require that the transporting protein be contained in a fluid hydrophobic environment. A speculative model of the membrane with a transport protein is shown in Figure 9. In this Figure it is assumed that binding of the lactose produces the loss of an otherwise exposed polar region of the protein, which could be accomplished if the lactose were so bound in a crevice in the protein as to be almost "buried" in the protein. The lactose binding should eliminate all exposed or "bare" polar groups

on the carrier protein, so that it can rotate or move in the lipid region without loss of hydrophilic solvation energy.

Not all the membrane systems we have studied show a high degree of fluidity. The membranes that appear to be most fluid (sarcoplasmic vesicles and axonal membranes) probably have particularly highly concentrated transport sites. It appears reasonable to conjecture at the present time that the highly fluid regions of membranes may be associated with sites for perpendicular transport, or at least certain types of perpendicular transport. (Chapman, 1968, has also suggested that fluidity may be necessary for diffusional processes in tissues.) Our conjecture has a corollary: high fluidity must also have one or more disadvantages; otherwise all membranes would be highly fluid. We suggest that one major disadvantage is that high fluidity is also associated with leakiness. In membranes in which little transport is required, or leakiness is disadvantageous, the membrane lipids may be less fluid.

There is evidence that fluidity in membranes may be regulated in response to environmental variables that would otherwise tend to change the fluidity. For example, as Chapman (1968) has pointed out, the proportions of unsaturated fatty acids in bacterial membranes, as well as in the membranes of the goldfish brain, increase when the external temperature is lowered, which may well be an adjustment to maintain membrane fluidity as the temperature is lowered.

Recent experiments by Fox (1969) also suggest a close connection between hydrocarbon chain unsaturation and perpendicular transport. This investigator studied the induction of lactose transport in an unsaturated fatty-acid auxotroph of $E.\ coli$. This bacterium requires an exogenous

FIGURE 9 Schematic and speculative diagram of a membrane structure, showing lipophilic protein D with polar lactose binding site E, to provide facilitated transport of lactose through the fluid hydrophobic region. A. Phospho-

lipids arranged in a bilayer. B. Protein. C. Lipopolysaccharides. D. Permease protein. E. Binding site. Note that lipopolysaccharides may not be present in the same bacterial membrane that contains the permease.

source of unsaturated fatty acid for growth (Silbert and Vagelos, 1967). Fox showed that, in the absence of exogenous unsaturated fatty acid, the lactose permease (M-protein) could be induced, but that this protein did not bind to the membrane in a functional form. On the other hand, in the presence of exogenous unsaturated fatty acid, the Mprotein could be induced and was functionally incorporated into the membrane. As a first crude approximation, we may therefore picture the unsaturated fatty acids as being incorporated in the membrane and forming a fluid pool in which the M-protein is dissolved.

Our conjectures regarding the localization of fluid hydrophobic regions in the vicinity of sites for perpendicular transport suggest a number of experiments. Three examples are enumerated below.

1. In bacteria in which transport sites in membranes can be induced in relatively large numbers, it may be possible to demonstrate a quantitative increase of the extent of fluid membrane regions associated with induction of transport with the use of a gratuitous inducer.

2. It may be possible to visualize perpendicular transport sites in membranes, in the electron microscope, by gentle treatment of the membrane tissue with detergents, lipid soluble materials, or both. Under these conditions it can be anticipated that such substances will bind preferentially to the most fluid regions of the membrane, producing recognizable distortions or imperfections in the vicinity of the transport sites.

3. It may be possible to obtain a direct demonstration of the relation between fluidity and perpendicular transport if one can obtain a "temperature sensitive" transport system that shows an abrupt change in transport versus temperature curve. In this case, spin labels localized in the transport region should show a correspondingly abrupt change in spectrum at the same temperature.

In conclusion, we may note that in our discussion we have assigned a very important but relatively passive role to membrane fluidity: the fluid hydrophobic region of a membrane makes it possible for a relatively rigid protein with a hydrophobic surface to rotate, be translated (or both), within the membrane. It is quite plausible that fluidity may also serve as a regulator or even a switch for biochemical and biophysical events in membranes. For example, an effector, a hormone, or both, may bind to a hydrophobic region, modify the fluidity, and increase or decrease the rate of membrane transport. Although we have no direct evidence for this effect at present, it is interesting to note that we have observed that DDT binds to phospholipids in a way that makes them less fluid, and this substance also prolongs the action potential of axonal membranes (Hubbell and Mc-Connell, unpublished).

The insect sex attractant bombykol (hexadeca-10-*trans*-12-*cis*-diene) has a chemical formula,

that suggests it may fluidize an otherwise nonfluid bilayer region of a membrane. This, in turn, could "free" a protein sodium carrier, leading to neural excitation, and appropriate response of the insect.

Photoisomerization of the visual pigment retinaldehyde could likewise change membrane fluidity, leading to membrane permeability changes, and excitation.

Although our discussion of the possible biological roles of molecular motion and fluidity in membranes is clearly somewhat speculative at the present moment, it is also clear that it suggests a number of definitive experiments whereby these speculations can be tested.

Acknowledgments

I am greatly indebted to my graduate students, Messrs. W. Hubbell, A. Horwitz, and R. Kornberg, for many helpful and critical discussions of the contents of this manuscript. Most of the experiments cited here have been carried out by Mr. Hubbell, and many of the ideas have been developed in discussions with him. Mr. A. Horwitz first brought the important works of F. Fox and of Silbert and Vagelos to my attention. The spin-label studies of the sarcoplasmic vesicle system by Mr. Kornberg and Mr. Hubbell have been a most significant contribution to our conviction that high fluidity in membranes is associated with perpendicular transport. Spin label III (5, 10) was first synthesized in my laboratory by Dr. Joachim Seelig, and I am greatly indebted to him for the sample used in the work described here. I am also indebted to Professor Paul Flory for a helpful discussion concerning barriers to internal rotation in hydrocarbon chains.

This work has been sponsored by the National Science Foundation under Grant GB7559, by the National Institutes of Health under Grant NB-08058-01, and by the Office of Naval Research under Contract No. 225(88), and it has benefited from facilities made available to Stanford University by the Advanced Research Projects Agency through the Center for Materials Research.

63 Evidence for Structural Changes During Nerve Activity and Their Relation to the Conduction Mechanism

R. D. KEYNES

THE MAIN PURPOSE of this article is to describe some recent work on the thermal and optical properties of stimulated nerves which was undertaken in the hope that it would throw some light from a fresh direction on the nature of the molecular events underlying conduction of the nervous impulse. But before this new experimental evidence is considered, it is necessary to summarize the two opposed views on the mechanism of excitation that currently hold the field.

The two stable-states theory

The idea has been proposed by Tasaki (1968) that the nerve membrane is to be regarded essentially as a fixed charge structure that can be switched between two different stable states. As I understand it, the genesis for this concept was the fact that, under certain conditions, the nerve membrane can generate greatly prolonged action potentials, from the plateau of which it can be triggered to revert abruptly and in all-or-none fashion back to the resting state in the same way as it does when the spike is initiated. Figure 1 shows an extreme example of this type of behavior. It was observed when a squid giant axon was first injected with tetraethyl-

FIGURE 1 The action potential recorded with an internal voltage wire in a squid giant axon containing 15 mm TEA and immersed in isethionate artificial sea water. Amplitude at peak was 95 mV. Time calibration bar = 0.5 sec. Temperature 12° C. (Cohen and Keynes, unpublished experiment.)

ammonium (TEA) ions to obtain the roughly tenfold prolongation of the spike described by Tasaki and Hagiwara (1957), and was then immersed in a solution in which nonpenetrating isethionate ions (Koechlin, 1955) had been substituted for the normal chloride. The further prolongation of the spike, by about two orders of magnitude, which resulted from this exchange of external anions does not seem to have been anticipated by Tasaki (1968), but it is readily understood from the alternative viewpoint as being the inevitable consequence of removing the principal source of ionic current for repolarizing the membrane. This source is an inward transfer of chloride in an axon in which the outward potassium current has already been blocked by TEA. It is not entirely clear whether the standard equivalent circuit is able, in its basic form, to account for the gradual buildup of oscillations during the plateau and the final regenerative repolarization seen under these abnormal conditions. However, there would be no difficulty in incorporating additional elements to explain this kind of behavior, such as a slowly inactivated or anomalous potassium conductance change.

It is impossible, in the space at my disposal, to examine the two stable-states theory in any detail, or to explain fully why I find it somewhat unsatisfactory. An essential feature of the theory is the role attributed to calcium ions, the displacement of which from association with the fixed negative charges in the membrane by potassium ions moving outward during the initial depolarization is supposed to characterize the "active" stable state, and the binding of which once more to the membrane then restores the "resting" stable state. Therefore, I would draw attention to the absence from the published accounts of the theory of any quantitative or even qualitative explanation for several generally accepted features of the action of calcium on excitable membranes. Although the theory might be expected to predict the observed rise in threshold of a nerve fiber with external $[Ca^{2+}]_{o}$, it would surely predict also that the duration of the active state, and hence of the spike, should decrease with rising [Ca²⁺]₀. In actual fact, the spike duration is normally independent of external calcium, and

R. D. KEYNES Agricultural Research Council, Institute of Animal Physiology, Babraham, Cambridge, England

it is only under severely unphysiological conditions that the spike can be shortened by raising the calcium level. Again, the well-documented finding (Frankenhaeuser and Hodg-kin, 1957) that, under a voltage clamp, changes in $[Ca^{2+}]_{o}$ shift the curves relating sodium and potassium conductance to membrane potential along the voltage axis without altering either their shape or the peak values of the conductances, has been ignored by Tasaki (1968). He also makes no attempt to account for the difference in magnitude between the amounts of sodium and potassium that are transferred across the membrane during a single impulse (of the order of 4 pmole/cm²) and the corresponding figure for calcium (shown by Hodgkin and Keynes, 1957, to be only about 0.006 pmole/cm²).

The ionic theory

The most widely accepted hypothesis to account for the properties of excitable membranes is that due to Hodgkin and Huxley, according to which the membrane can be regarded as possessing a capacitative element (Figure 2), in

FIGURE 2 Equivalent circuit for an excitable membrane. In order to account for such phenomena as pacemaker activity and anomalous rectification, R_{Na} and R_{K} have each been shown as two variable resistors in parallel, which might behave as different functions of potential and time and be differently affected by drugs.

parallel with which there are batteries representing the Nernst equilibrium potentials E_{Na} and E_K for sodium and potassium ions, each in series with variable resistances. An additional battery and a fixed "leak" resistance R_L are also included to cover the contribution to the membrane current, which is relatively small, from Cl⁻ and other uniden-

tified ions. In order to account for the electrical events during excitation, it is proposed (for a general review of the theory, see Hodgkin, 1964) that R_{Na_1} and R_{K_1} go through a sequence of voltage-dependent and time-dependent changes. It is not necessary to describe in detail here the mathematical formulation of the hypothesis in terms of equations governing the sodium and potassium conductances that incorporate three coefficients that are continuous functions of membrane potential and time. It will suffice to note that the theory has successfully survived the tests of predicting from voltage-clamp data the behavior of the propagated action potential under a wide variety of conditions and of predicting from purely electrical measurements a correct value for the chemically determined ionic movements during the impulse.

It must be emphasized at this point that a description of the electrical properties of the nerve membrane, however complete and accurate it may be, does not provide any direct information about the nature, at the molecular level, of the events involved in the changes of ionic permeability. Certain features of the Hodgkin-Huxley equations, however, do have implications for the underlying molecular mechanism that should not be overlooked. Possibly the most important of these is the steepness of the conductancevoltage relationships in the neighborhood of the normal resting potential, an e-fold increase in conductance corresponding to a depolarization of only 4 or 5 millivolts (see Hodgkin, 1964). This means that the permeability must be controlled either by the displacement or reorientation of a single particle carrying as many as six negative charges, or by a mechanism involving the simultaneous redistribution of an equal number of singly charged groups or a correspondingly greater number of groups whose effective charge is less than one. The former possibility seems unlikely, but has not yet been ruled out experimentally (see Hille, 1970).

Na and K channels: common or separate?

Two questions that are highly relevant to any consideration of possible conformational changes in excitable membranes are, first, whether the sodium and potassium ions pass through the same or separate channels and, second, how many channels there are. Both problems have recently been discussed by Hille (1970), to whom reference should be made for a full presentation of the arguments. There seems little doubt that the sodium and potassium channels are distinct entities. Thus, treatment of nerve membranes with the Japanese puffer-fish poison tetrodotoxin (TTX) totally blocks the sodium channels without affecting in any way the behavior of the potassium channels, and, conversely, TEA strikingly reduces the potassium conductance without altering the sodium conductance. Several other approaches, such as a detailed consideration of the ionic selectivity of the membrane, of the action of calcium, of the degree of interaction between individual ions traversing the membrane, and of the relative numbers of channels, all lead to the same conclusion.

The number of channels

From measurements of the amount of TTX removed from a small volume of a dilute TTX solution by passing several lobster-leg nerve trunks through it, Moore et al. (1967) concluded that not more than 13 TTX molecules were taken up by 1 μ m² of membrane. If, as seems reasonable, this figure is taken to represent the number of sodium channels, it may appear surprisingly small. But it is large compared with that for sodium-pump sites in cells like erythrocytes, in which there is only about one ouabain-binding site per μ m² (see, for example, Ellory and Keynes, 1969); and Hille (1970) has argued that it is not incompatible with the evidence from other directions. Taking the peak sodium conductance of a lobster axon as 0.53 mho/cm² (Narahashi et al., 1964), the conductance of a single channel comes out as 0.4 nmho. It may be no more than a coincidence, but this is precisely the value obtained by Bean et al. (1969) for the quantal increase in conductance when the so-called "excitability inducing material" is incorporated into phospholipid bilayers. In the squid giant axon, the peak sodium conductance is slightly smaller than it is in the lobster axon (0.12 mho/cm^2), so that the packing density of sodium channels is only of the order of 3 per μ m². The number of potassium channels is rather uncertain, but their conductance is probably much lower than that of the sodium channels, and there are correspondingly more of them, perhaps by a factor of 50 (Hille, 1970). The importance of these numbers in the present context lies in a comparison with the number of phospholipid molecules in the membrane, which, if the area of a single molecule is 50 Å², is no fewer than 2×10^6 per μm^2 of each surface. One cannot avoid the conclusion that, because the current-carrying channels are evidently so sparsely distributed in the membrane, it will be much more difficult to detect conductance-linked conformational changes taking place only at these special places than potential-linked effects that might involve all, or at any rate a majority, of the molecules present.

Entropy changes during nervous activity

Recent measurements of the temperature changes during the conduction of impulses along the nonmyelinated fibers of the cervical vagus nerve of rabbit have shown that, as illustrated in Figure 3, the upstroke of the action potential is accompanied by a liberation of heat, most of which is then reabsorbed during the downstroke (Howarth et al., 1968). After allowing as well as possible for the effects of overlap between the downstroke of the spike in the fibers that conduct fastest and the upstroke in the slower ones, we estimated that the quantity of heat released during the upstroke of each impulse was 24.5 μ cal/g. The "negative" heat during the recovery phase was 22.2 μ cal/g, leaving a net initial positive heat of 2.3 μ cal/g. The question then arose of explaining these results in terms of the events known to be taking place during the conduction process.

The first possibility to be examined was whether the heat of exchange of sodium and potassium could account for the initial heat. This idea could be quickly dismissed, because for 0.15 M solutions the heat of ionic mixing is only of the order of 10 cal/mole of Na or K, so that the observed exchange of 12 n-mole/g impulse (which was determined with 42 K) would not produce more than about 0.12 μ cal/g impulse. A more promising candidate would be the heat of displacement by the K+ ions of Ca2+ ions bound to membrane-fixed charges; that heat is likely to be positive and of the order of several thousand calories per mole (Coleman, 1952). One could account completely for the initial heat by an exchange of this kind only if all the K⁺ ions lost from the nerve during the impulse were involved in it. For reasons already discussed, this is not an acceptable proposition. However, it is not impossible that a K+-Ca²⁺ exchange does make an appreciable contribution to the initial heat.

Another obvious source of heat is the liberation by circulating currents of the electrical energy $(=\frac{1}{2}CV^2)$ stored in the membrane capacity (C) when the resting potential (V) is discharged. The membrane is then repolarized at the expense of the thermal energy of some of the ions in the surrounding solutions, so a corresponding quantity of heat would be reabsorbed during the recovery phase of the spike. But this "condenser theory," although it fits the facts extremely well as far as the timing of the positive and negative initial heats is concerned, does not properly explain

FIGURE 3 The temperature changes during the passage of an impulse along a nonmyelinated nerve trunk. The superimposed blocks show the computed evolution and subsequent reabsorption of heat. (From Howarth et al., 1968).

their magnitudes. There is some doubt as to what values of C and V should be used for the calculation, but, even on the most generous assumptions, $\frac{1}{2}$ CV² cannot account for more than 11 μ cal/g impulse.

We believe that the discrepancy is to be explained by the occurrence of an appreciable decrease in the entropy of the membrane when the potential across it is *reduced*. This is an effect in the opposite direction to that which would obtain if the dielectric behaved like a simple liquid, but the rather meager evidence on the effect of temperature on the capacity of nerve membranes and phospholipid bilayers supports the view that in such membranes the entropy change would be of the right order of size and in the right direction to fit the experimental observations. This argument does not, unfortunately, enable us to identify the type of conformational change that is presumably involved, and all that can be said is that it is unlikely to be confined to the sodium channels, because a positive heat of 25 μ cal/g liberated at 13×10^8 channels/cm² in a nerve containing 6000 cm² membrane/g would correspond to 3 \times 10⁻¹⁸ cal/channel, or 2×10^6 cal/mole if there was one transport molecule at each channel. On the other hand, the same positive heat distributed among all the phospholipid molecules would give only 6 cal/mole, which can hardly be regarded as an improbable figure for an oriented molecule subjected to a voltage gradient of the order of 40,000 V/cm.

Birefringence changes in excitable membranes

Optically detectable changes in excitable tissues have recently been observed by studying (1) birefringence, (2) light scattering, and (3) fluorescence emission from nerves stained with fluorescent dyes (Cohen and Keynes, 1968, 1969; Cohen et al., 1968, 1969; Tasaki et al., 1968; Carnay and Barry, 1969). The most straightforward of these approaches is the measurement of birefringence. The results obtained when nerves and slices of electric organ are mounted between a crossed polarizer and analyzer at 45 degrees to the plane of polarization, and illuminated brightly with white light, are described first.

Figure 4 shows a typical record of the change in light

FIGURE 4 Birefringence (thick line) and the action potential (thin line) in a squid giant axon. The arrow represents a light increase of 5×10^{-6} /impulse. Temperature, 7° C. (From Cohen et al., 1968.)

intensity during the passage of an impulse along a squid giant axon mounted on the stage of a polarizing microscope. The optical change is seen to follow very closely the membrane potential recorded with an intracellular electrode at the center of the illuminated region. A similar correspondence between the optical and electrical signals was observed in the small, nonmyelinated fibers of crab-leg nerve, the abdominal vagus nerve of rabbit, and in quite a different type of excitable tissue, the electric organ of the electric eel (Figure 5). An important point to establish at the outset was

FIGURE 5 Birefringence changes during the discharge of *Electrophorus* electroplates. Upper records: Birefringence with and without optical compensation. Middle records: The action potential as recorded, and corrected for the stimulus artifact. Bottom records: Evidence that the birefringence follows the membrane potential change with a time constant of about 55 μ sec. (From Cohen et al., 1969.)

that the change in light intensity did represent a change in birefringence and not a change in absorption or scattering of light. That such was indeed the case is proved by the top records in Figure 5, which show that, when optical compensation was introduced to subtract 150 nm of retardation from the 75 nm resting retardation of the tissue, the signal was the exact inverse of that without compensation. The squid giant axon gave precisely the same result when an appropriate compensator was inserted in the light path. Except under favorable conditions, the changes in light intensity were too small to be distinguished properly from the random fluctuations in the resting intensity during a single sweep, and signal averaging devices were therefore used in order to improve the signal to noise ratio. In the squid axon the light intensity decreased by about one part in 2×10^5 at the peak of the spike, and several thousand sweeps were averaged. In the electric organ the light intensity increased by about one part in 2×10^3 , and it was necessary to average only 50 to 100 sweeps.

The localization of the birefringence change in the membrane or its immediate vicinity was established by two kinds of experiment. About half of the resting birefringence of the squid axon arises from longitudinally orientated filaments in the axoplasm; but, when most of the axoplasm was removed by the "garden roller" technique (Baker et al., 1961) and the axon was perfused with a buffered solution of potassium fluoride, the change in birefringence during the spike was unimpaired. On several occasions we used a light stop at the image plane of the microscope to examine only a selected region of the axon, and established that a strip including 100 μ M of an edge of a 1000- μ M axon gave at least 20 times as large a fractional change in intensity as a strip covering the central 500 µM of the same axon. It follows that the birefringence change has a radial optic axis and arises from sources disposed in a cylindrical region at the outer edge of the axon or in the sheath (including the Schwann cell). We tentatively assume that, in fact, the change takes place either in the phospholipids of the membrane itself or in proteins or other molecules adsorbed to its surface. Although the Schwann cell certainly contributes substantially to the resting birefringence, it seems unlikely that it is responsible for the changes during activity, partly because the voltage drop across it is much smaller than that across the membrane, and partly because large birefringence changes are observed in the electric organ and frog muscle fibers in which there are no Schwann cells. By using the data of Schmitt and Bear (1939) for the absolute magnitude of the birefringence of cell membranes, it can be calculated (Cohen et al., 1968) that at the peak of the spike the intrinsic radial birefringence of the squid axon membrane is increased by about 0.15-0.5 per cent. In the electric organ the retardation is decreased by about the same amount, but there is not necessarily a contradiction in the direction of the change, for, in this case, there is considerable uncertainty as to the predominant orientation of the membrane, because the innervated faces of the electroplates are crowded with so many papillae and fine tubules.

The observations described so far suggest that the birefringence change was primarily a voltage-dependent phenomenon, but in order to place this conclusion on a firm basis it was essential to make observations under voltageclamp conditions. Figure 6 shows that a square hyperpolar-

izing voltage pulse gave a roughly square birefringence response, and a depolarizing pulse gave a somewhat less square response. The departure from rectangularity of the response to depolarization was almost certainly due to the employment of a clamping circuit that did not allow for the series resistance of the Schwann cell. In all later work, electrically "compensated" feedback was used, and it became clear that, if there was a component of the birefringence change linked with ionic current flow or conductance, it was relatively small in comparison with the voltagedependent effect. Experiments of this kind made it possible to study the quantitative relationship between birefringence and membrane potential, and it was established that, as expected, the relationship was a good approximation to a square law. However, the birefringence was not, as might have been predicted on the simplest basis, symmetrical about zero membrane potential, but about a potential displaced some 100 mV beyond zero in the depolarizing direction, i.e., inside positive. There is evidently some kind of electrical or structural asymmetry in the membrane. This aspect of the work seems one of the most promising for further study.

Another important parameter of the birefringence change that could be studied under a voltage clamp was its time constant or relaxation time. At 15° C, the relaxation time was about 30 μ sec, and, although the absolute size of the birefringence change varied very little with ambient temperature, the relaxation time had a large temperature coefficient and was considerably greater at 5° C. The electric organ appeared to have a very similar relaxation time. Time constants of this order of size would require the orienting molecules or side chains to be improbably large if they were moving freely in water, and their environment must therefore be relatively viscous.

One further observation that must be mentioned is that in the presence of 60–150 nm tetrodotoxin or 300 nm

FIGURE 6 Changes in birefringence of the squid giant axon under a voltage clamp. Upper trace: Birefringence, the arrow representing an increase in light intensity of 1×10^{-5} . Middle trace: Membrane potential. Lower trace: Membrane current. Uncompensated feedback was used to clamp a 10-mm length of axon. Temperature, 17° C. (From Cohen et al., 1968.)

saxitoxin, the changes in birefringence for voltage-clamp pulses were doubled or quadrupled in size, while at the same time the relaxation time lengthened to an early component of 100–200 μ sec followed by a late one of 2–3 msec. This striking and quite unexpected effect was not associated directly with the blocking action of the toxins because sometimes it did not manifest itself until several minutes after the sodium current had fallen to zero; conversely, when the toxin was washed away, the effect persisted for some time after the sodium current had recovered. As has already been seen, the numbers of toxin molecules taken up by the membrane at these low concentrations are apparently very few, and the effect of TTX on birefringence is all the more surprising. The effect of these and other molecules when adsorbed to the membrane will clearly repay further detailed examination.

Changes in light scattering during nervous activity

The starting point for our recent work on optical changes in excitable tissues was an attempt to follow up the observations on light scattering in crab nerves made by Hill (1950) and Tobias (1952). The occurrence of relatively long-lasting light-scattering effects, apparently associated with a transient and still not properly explained swelling of the axons, was confirmed (Figure 7), but we were soon diverted from examining these slow changes by the discovery that there was also a fast change in light scattering, the time course of which was not unlike that of the action potential. The effect was a small one, the light scattered at 90 degrees increasing by

FIGURE 7 Light scattered at 90 degrees by a crab-leg nerve stimulated 15 mm from the illuminated region. The vertical arrow represents an increase of 2×10^{-5} /impulse: a, in artificial sea water with refractive index of 1.339; b, dextran added to give a refractive index of 1.353; c, the compound action potential recorded 10 mm beyond the illuminated region. Temperature, 18° C. (From Cohen et al., 1968.)

about one part in 20,000 for a single impulse, but by averaging 25 to 200 sweeps with a CAT computer, an acceptable signal-to-noise ratio could be attained. Apart from verifying that the change was reversed in direction when the light scattered forward instead of at right angles was measured, and showing that its size (expressed as $\Delta I/I$, in which I is the resting intensity) varied approximately as the reciprocal of (wave length)², it was not possible to make much progress in analyzing the light-scattering effect without studying it under voltage-clamp conditions. However, it turned out that similar effects could be observed in the squid giant axon, which enabled us to learn a little more about their origin.

As can be seen in Figure 8, the time course of the early changes in light scattering during propagation of an impulse along a squid axon bears some relation to that of the spike, but it is clear that several components are involved, and the record obtained at 90 degrees is not exactly the inverse of that at 35 degrees. One component appears to be voltagedependent, which is most easily seen when a hyperpolarizing voltage-clamp pulse is applied and there are no large ionic currents flowing through the membrane (Figure 9). It seems to differ in origin from the voltage-dependent

FIGURE 8 Light scattered at three different angles by a squid giant axon during a propagated impulse. Temperature, 13° C. (Cohen and Keynes, unpublished experiment.)

FIGURE 9 The voltage-dependent component of the lightscattering change in a squid giant axon, recorded at 35 degrees to the incident illumination. Compensated feedback was used, and the voltage pulse was in the hyperpolarizing direction. Temperature, 12° C. (Cohen and Keynes, unpublished experiment.)

birefringence change, because its relaxation time is appreciably greater (around $100 \ \mu sec$) and it is unaffected by TTX. Then there are current-dependent components the sizes of which at the end of a voltage-clamp pulse are roughly proportional to the integrals of inward sodium current and outward potassium current. These can be abolished or reduced in size by treating the axon with TTX or TEA. There are also slower changes that persist after the passage of an impulse or the end of a voltage-clamp pulse, which have not yet been studied in any detail. Disappointingly, we have so far been unable to identify any light-scattering change of which the time course would fit with either the activation or the inactivation of the sodium and potassium conductances.

It seems probable that the current-dependent components and the slower effects arise from alterations in the refractive indexes and physical dimensions of various parts of the complex system that we are studying. Thus the concentrations of sodium and potassium in the space between the axon membrane and the Schwann cell are temporarily changed when current flows, with consequent movements of water and swelling or shrinking of the space. Similar light-scattering effects have been observed in the electric organ (Cohen et al., 1969), with one component that could plausibly be attributed to comparable effects involving the microtubules that invaginate the membrane. Attempts to correlate the time constant for recovery of the light scattering after a pulse of current with the time constant identified by Frankenhaeuser and Hodgkin (1956) as that for diffusion of potassium out of the Schwann cell space, have not been successful. By studying the dependence of all these changes on the scattering angle, and by altering such factors as the refractive index of the external medium, we should eventually find it possible to determine their precise location and cause, but the task is not an easy one.

Changes in fluorescence emission

It has been reported by Tasaki et al., (1968, 1969) that nerves stained with the fluorescent dyes 8-anilinonaphthalene-1sulphonic acid (ANS) and acridine orange (AO) exhibit a small increase in fluorescence emission during the passage of an impulse. Carnay and Barry (1969) have since found that frog-muscle fibers stained with pyronine B give a decreased emission during the spike itself, followed by a somewhat larger increase in emission during the after-potential and period of latency relaxation. The fact that in nerve the change in light intensity was in the same direction for fluorescence emission as it was for 90-degree light scattering and had a similar time course (Tasaki et al., 1968) might suggest that the fluorescence effect was some kind of scattering artifact. But in muscle, both the directions and the time courses of the two effects were different (Carnay and Barry, 1969), which seems to dispose of this possibility.

The records published by Tasaki et al. (1969) for squid axons, and the similarity between the time courses of the birefringence and fluorescence emission changes observed in muscle by Carnay and Barry (1969), suggest that membrane potential is the main factor affecting fluorescence emission. Fluorescence must be studied under voltageclamp conditions, however, if the precise origin of the changes in emission is to be determined. It is also clear that the nature of the dye with which the tissue is stained is of cardinal importance in any interpretation of the results of fluorescence measurements, because pyronine B gives a decrease in emission whereas ANS and AO give an increase. When the dye molecule can be tailor-made so that it is incorporated into the membrane structure in a predictable fashion, with the fluorescent group located in a specific region, studies of fluorescence emission will clearly become a valuable tool for probing the structural changes associated with nerve activity.

Conclusions

Two distinctly different types of structural change have been detected in excitable tissues by optical means. In the first place, there are potential-dependent changes in birefringence and light scattering that can be seen in untreated tissues, and changes in fluorescence emission, probably similar in origin, that are seen after staining with appropriate dyes. These effects are presumably confined to the

membrane, because only in its immediate neighborhood are the potential gradients really large, but there is little indication as to which part of the membrane is involvedthe phospholipids of the membrane interior, or the proteins and other macromolecules of the membrane surface. Nor is it clear whether the potential-dependent changes arise primarily from reorientation of charged side groups in the electric field, as in the Kerr effect, or from a compression of the membrane by the attractive force exerted between the charges on its opposite sides. Second, there are currentdependent changes in light scattering and possibly in fluorescence emission as well. In all probability, these do not involve the membrane itself, but rather any external compartment from which the movement of ions is diffusion-limited, such as an endoplasmic reticulum communicating with the surface only through narrow channels, or the Schwann-cell space in the squid giant axon. In addition, there are relatively slow light-scattering changes, which appear to involve water movements into and out of the fibers, the origin of which has not yet been explored in detail.

Although we have done our best to find them, no optical effects have yet been observed that can be correlated definitely with alterations in membrane conductance. Perhaps this is not really surprising, in view of the enormous numerical disparity between the special sodium and potassium channels and the phospholipid and other molecules of which the general membrane structure is built. At these special sites there must surely be large conformational changes accompanying or causing the sequence of ionic conductance changes that take place during excitation and the propagation of an impulse, but they will be very hard to detect optically against a noisy background, and will produce a much smaller signal than any change affecting the whole membrane. It must therefore be concluded with reluctance that this approach is unlikely to yield direct evidence about the nature of the conformational changes at the active sites. However, it should give valuable information about the way in which the components of a cell membrane are affected by alterations of the electric field, and such knowledge is essential for the formulation of hypotheses concerned with the molecular basis of the mechanism of excitation.

64 The Ultrastructure of Synapses

J. DAVID ROBERTSON

THE SUBJECT OF synaptic ultrastructure has been reviewed several times in recent years (Gray, 1966; Gray and Guillery, 1966; Couteaux, 1963; De Robertis, 1959; Palay, 1956). This review, because of space limitation, is highly selective and does not attempt to cover the field. It aims at a description of the ultrastructure of selected synapses in both vertebrate and invertebrate nervous systems, with emphasis on structural features that can be directly related to function.

Structures related to chemical transmission

The first electron micrographs of motor end plates were reported in abstract form in 1954 (Palade and Palay, 1954; Reger, 1954; Robertson, 1954). The complete reports of two of these papers soon followed (Reger, 1955; Robertson, 1956b). The major features of the electron micrographs are indicated diagrammatically in Figure 1. The terminal axon is filled by about 300- to 500-Å, membrane-limited, synaptic vesicles. A gap of about 500 Å separates the presynaptic and postsynaptic membranes, and the gap is filled by dense material continuous with the basement lamina of the muscle fiber and that surrounding the terminal Schwann cell of the nerve. The basement lamina also extends into the junctional folds. Here the enfolded unit membranes (Robertson 1956b, 1960, 1964) are brought into apposition with a gap approximately 500 Å wide that is expanded slightly in the bottom of the fold. The junctional folds in rat and lizard endings are very complicated and extend in branching arrays all over the nerve terminals.

In a study of the vertebrate central nervous system in 1956, Palay clearly identified synaptic boutons and established that they contained accumulations of mitochondria and also the characteristic synaptic vesicles reported in motor end plates (Palade and Palay, 1954; Robertson, 1956b) and other synapses (De Robertis and Bennett, 1954, 1955; Fernández-Morán, 1955). Palay recognized the vesicles as likely bearers of packets of neurotransmitters, the presence of which in motor end plates had been suggested by Fatt (1954). Castillo and Katz (1954, 1956) had shown that characteristic, sudden changes in membrane potential occurred randomly at motor end plates at a frequency of a few milliseconds. The term miniature end-plate potential (MEPP) was applied to these spikes because they resembled the postsynaptic end-plate potential produced by discharge of the nerve to the ending, although they are much smaller. Their amplitude was approximately 0.1 to 0.5 millivolt, and their duration was only a few tenths of a millisecond. It was found, by the use of external microelectrodes, that the application of acetylcholine (ACh) to the surface of the presynaptic muscle fiber near the ending produced a potential change exactly equivalent to that of the MEPP, and a much larger amount produced a propagated actionpotential spike. ACh was assumed to be released by the terminal nerve fiber as a transmitter, and it was also assumed that it was being continuously released in small packets, each producing one MEPP. The action potential was supposed to be the result of a massive synchronous release of these quanta.

The concept of quantal release of a neurotransmitter originated with this work. It seemed to be a reasonable analysis, but I did not find it an entirely satisfactory one for several reasons. For instance, it was apparent that, as its ACh was released, the membrane of the synaptic vesicles would, of necessity, have to become incorporated into the axonal membrane, which, as its surface area increased, would rapidly be converted into a membrane identical with that surrounding the vesicles. This seemed improbable, and it was subsequently proved incorrect as a general notion by Whittaker (1966), who showed that the membrane of the synaptic vesicle.

In reviewing the above events, I have touched on the groundwork for much of current synaptology at the ultrastructural level. Thus, the synaptic vesicle, concentrated presynaptically, has become an almost necessary feature of a synapse; the notion of quantal release of transmitter by fusion of vesicles with the synaptic membrane is widely accepted, and the association of chemical transmission and a fairly wide synaptic gap is now known to be a characteristic feature of many kinds of putative chemical synapses. I turn now to a different kind of structural differentiation that is not associated with chemical transmission.

Morphological changes in membranes resulting from electrical stimulation

In recent work, Dr. Camillo Peracchia (1969), in my laboratory, has observed a hexagonal pattern in *en face* views of

J. DAVID ROBERTSON Department of Anatomy, Duke University Medical Center, Durham, North Carolina

FIGURE 1 Interpretative diagram of a motor end plate in Anolis carolinensis. The surface membrane complexes (SMCs) of the Schwann cells (S.c.), muscle fiber (m.f.), and endoneural sheath cells (endo.) are shown. The muscle surface is thrown into junctional folds to make the subneural apparatus of Couteaux. The five layers of the SMC that separate terminal axoplasm from sarcoplasm are shown. The main features of terminal axoplasm and sarcoplasm are

indicated. The region marked by the circle is enlarged to show more detail. The continuities between the membrane structures at the region marked "?" was somewhat interpretative, as was also the identification of Schwann cytoplasm at the time this diagram was constructed, but subsequent work has established the correctness of the interpretation. Magnification, \times 60,000.

the synaptic membrane complexes (SMCs) of the lateral giant septal synapses of the crayfish, as indicated in Figure 2. The center-to-center spacing of the hexagonal facets is about 250 Å. In the median-giant-to-motor synapse (MGM), he has found another feature that may be related to this hexagonal pattern. Occasionally a peculiar scalloping of the synaptic membranes is seen in these synapses after certain special procedures. Here the membranes are alternately slightly separated and in very close contact. The repeat period of this scallop is, again, about 250 Å. It should also be noted that Peracchia has isolated certain membrane fragments from the crayfish ganglia by a special freezeshatter method devised by Dr. Juan Vergara. He has found

in these fragments a very regular hexagonal pattern in which the facets show a center-to-center spacing of about 150 Å. One of these micrographs is shown in Figure 3. It is too early to say where these fragments may have originated and what relationship, if any, they may have to the hexagonal pattern seen in the SMCs.

Peracchia has recently conducted some experiments designed to see whether structural alterations, demonstrable by the electron microscope, take place in the MGM synapses with activity. He has succeeded in eliciting and identifying a specific morphological response in electrically stimulated fibers. It appears frequently with stimulation and never in control animals. The abdominal nerve cord is per-

fused with glutaraldehyde during stimulation of one of the circumesophageal commissures at a frequency of 30 to 40 per second and a strength of approximately 10 volts. After some hours in glutaraldehyde, the nerve cord is post-fixed

FIGURE 2 (*Above*) Section of lateral giant septal synapse in crayfish nerve cord, including synaptic membrane complex in an *en face* view. Note the hexagonally arranged spots spaced at a center-to-center distance of about 250 Å. Magnification, \times 170,000.

FIGURE 3 (Left) Hexagonal pattern in a membrane fragment isolated from crayfish nerve cord by C. Peracchia. Center-to-center spacing of the hexagons is about 90 Å. PTA-negative stain preparation. Magnification, \times 170,000.

with OsO₄, according to the usual routine procedures. A distinct morphological change appears selectively in the stimulated cords.

Figure 4C shows both a stimulated fiber (the giant fiber,

FIGURE 4 Stimulated crayfish giant nerve fiber (above), with two unstimulated small fibers (below). Fixed with glutaraldehyde- OsO_4 and stained with lead citrate. Note the increased density of the membranes of the giant fiber.

above) and two smaller unstimulated fibers (below). An obvious, clearcut difference between the two is apparent. All the membranes of the stimulated fibers appear to be very dense. This phenomenon occurs if the perfusion of the stimulated nerve cord is begun after as few as 30 to 40 propagated impulses have been set up. The densification occurs in all the unit membranes bounded by axoplasm, including the surface membrane, endoplasmic reticulum and vesicle membranes, and the outer mitochondrial membranes. It is caused by the appearance of a dense amorphous material that effectively increases the thickness of the inner and outer dense leaflet (inset, Figure 4A, B). The inner one is increased by approximately 300 to 500 per cent; the outer, about 50 to 100 per cent. The material added to the membrane leaflets is not seen after glutaraldehyde fixation alone. If sections of the ganglion are treated with peroxide after osmium fixation, the dense material disappears. Apparently it represents a deposition of reduced osmic reaction products.

The insets (A and B) of a mitochondrion show the dense material that increases the thickness of inner and outer leaflets of the outer membrane only. Magnifications, $\times 10,000$; inset A, $\times 90,000$; inset B, $\times 180,000$.

The reaction can be regarded as indicative of an increased osmiophilia of the membranes. At first it was thought that the dense material might be calcium (Peracchia and Robertson, 1968; Peracchia, 1969), but it did not show up after glutaraldehyde fixation alone, which seemed to rule out calcium. It is known from the work of Huneeus-Cox et al. (1966) that there is a protein in giant invertebrate nerve fibers that contains sulfhydryl groups, and that these groups can be reversibly bound by certain organomercurials, with consequent reversible blocking of impulse conduction. Sulfhydryl groups are known to react vigorously with OsO_4 , but in oxidized form these groups are nonreactive.

The possibility then arose that a protein high in disulfide groups was present mainly in or on the membrane leaflets and was affected by impulse propagation in such a way that the disulfide groups were reduced. To test whether the osmiophilia might be due to such a protein, Peracchia treated unstimulated glutaraldehyde-fixed nerve fibers with thioglycollate in an effort to reduce disulfide groups before osmication. It was expected that an increased osmiophilia would appear as a result of the thioglycollate. Such proved to be the case, as indicated in Figure 5.

To carry the analysis a step further, Peracchia followed the glutaraldehyde-thioglycollate treatment with N-ethyl maleimide (NEM) before OsO_4 . NEM binds sulfhydryl groups and makes them inaccessible to reaction with OsO_4 . After this procedure, the osmiophilia presumably conferred by the thioglycollate is lost, as indicated in Figure 6. It thus appears reasonable to conclude that, during action-potential propagation, disulfide groups in a protein lying either on or within the cytoplasmic leaflet of the axon-unit membranes, as well as, to a lesser extent, on or within the outer leaflet, undergo a change whereby they are converted to sulfhydryl groups. It should be emphasized that this reaction never occurs in Schwann-cell membranes and can be elicited in axon membranes only by active stimulation during perfusion with glutaraldehyde or by treatment with thioglycollate. It thus appears that a meaningful morphological change is frequently demonstrable in electrically stimulated nerve membranes and that this change could conceivably be used as a morphological tag of active neurons in a neuropil, if it can be shown to be related to activity irrespective of electrical stimulation.

That the effect observed by Peracchia involves all the membranes bounded by axoplasm is interesting. One explanation may be simply that all these membranes are neuronal, and, although doubtless chemically specific, they may have at least one property in common, i.e., the presence of the sulphur-rich protein in question. Another way to explain the phenomenon is to assume that this compound is in solution in axoplasm and that all membranes in contact with axoplasm tend to adsorb some of it.

FIGURE 5 Crayfish nerve fiber treated with thioglycollate after fixation with glutaraldehyde but before postfixation with OsO_4 and lead staining. Note the dense amorphous material causing thickening of the axon membrane and the

outer mitochondrial membrane. Compare this with the stimulated nerve fiber in Figure 4 and note the similarity in appearance, even though the thickness of the dense precipitate here is exaggerated. Magnification, $\times 140,000$.

FIGURE 6 Crayfish nerve fiber treated with thioglycollate after fixation with glutaraldehyde and then with NEM before fixation with OsO_4 and lead staining. Note that this fiber resembles the control unstimulated nerve fibers

shown in Figure 4. It is believed that the thioglycollate first reduced disulfide groups to produce sulfhydril groups that were then bound up by NEM, making them inaccessible to reaction with OsO_4 . Magnification, \times 21,000.

Electrical synaptic transmission in invertebrates

The giant fiber synapses in the ventral nerve cord of the crayfish (Johnson, 1924) were the object of one of the earliest studies of synapses by electron microscopy (Robertson, 1953). This work has been reviewed fairly recently (Robertson 1961, 1964), and hence is treated here only briefly. The main point is simply that in these synapses the gap between presynaptic and postsynaptic membranes was occluded. Furshpan and Potter (1959) showed that transmission at these synapses is by an electrical mechanism, and the occlusion of the synaptic cleft was believed to offer a structural counterpart to this physiological feature. It was also noted that synaptic vesicles were not a prominent feature of these electrical synapses, although some clear vesicles about 300 to 500 Å in diameter were present. Aggregates of mitochondria were noted in postsynaptic axoplasm and rows of vesicles were sometimes seen close to both presynaptic and postsynaptic membranes. These aligned vesicles were spaced at intervals of 0.1 to 0.2μ . In the case of the lateral giant septal synapses that were physiologically unpolarized, the synaptic cleft is not completely occluded; there is a gap approximately 20 Å wide.

The presence in an electrical synapse of vesicles superficially indistinguishable from the synaptic vesicle seen in neurohumoral synapses poses an interesting enigma. This is, in fact, another reason I have always had some reservations about the idea of quantal release of transmitter from vesicles. Certainly it suggests that the mere presence of vesicles does not necessarily mean the presence of chemical transmitters packaged within them. Indeed, their exact function cannot be specified on present evidence. One may speculate, perhaps, by saying that unit membrane vesicles are universal components of axoplasm and that they tend to concentrate at synaptic membrane complexes (SMCs) because there is something special about the electric field

changes in such loci caused by the close apposition of two nerve membranes conducting action potentials. It is only in this region that two nerve membranes are in close apposition. Elul (1966, 1967) has recently shown that nerve membranes move toward a microelectrode tip if positive current is flowing from it. The currents involved are comparable to those that flow during action-potential propagation. The observed membrane movement was explained as being caused by their possessing a negative fixed charge. If one assumes that both the inside of the nerve membrane and the cytoplasmic side of the vesicle membrane have a fixed negative charge, vesicles ordinarily would not approach the membrane closely except during the current flows associated with action-potential propagation. Because this is ordinarily diphasic, one might expect little net effect on vesicles except, perhaps, at synapses, where one might imagine that special features of current flow may exert a net attractive electrophoretic effect leading to the vesicles becoming concentrated passively in this region. If this is so, the vesicles might-at least in some cases-have little or nothing to do with synaptic transmission. Another obvious, nonspecific way to explain the presence of vesicles in boutons is to note that these are nerve terminals. Axoplasmic flow might thus propel and trap them there. However, this would not explain their presence near the SMC of the crayfish MGM synapses.

In MGM synapses, another type of synaptic bouton is present on the synaptic processes themselves. They are packed with typical synaptic vesicles and in some cases contain glycogen particles, but there is never an occlusion of the presynaptic and postsynaptic membrane cleft, which is 100 to 150 Å wide, regardless of fixation method. The origin of these boutons is unknown. At one time they were thought to come from the adjacent motor fiber (Robertson, 1961), but serial sections failed to confirm this. The synapse shows neither dense material in the presynaptic or postsynaptic axoplasm near the synaptic membranes nor a condensation in the synaptic cleft. These might be inhibitory neurohumoral synapses, but this is complete speculation.

Electrical synaptic transmission in vertebrates

I now review briefly a few relevant points in some work that has been reported elsewhere (Furshpan and Furukawa, 1962; Robertson, 1963; Robertson et al., 1963) on the club endings on the Mauthner cell lateral dendrite. Furshpan and Furukawa (1962) showed that the club endings transmit by an electrical mechanism, and we have produced morphological evidence that is consistent with this finding. These endings are characterized by SMCs that show disklike regions of complete closure of the synaptic cleft. Such a synaptic disk is seen diagrammatically in Figure 7A-E. In A and B, the disk is shown sectioned perpendicularly. In C it is slightly tilted. Here we see lines that repeat at a period of about 90 Å. As the disk is tilted still farther, as in D, one begins to see rows of dots between these lines. In the synaptic disk tilted completely on its side and thus viewed en face, as in E, one sees a regular honeycomb arrangement of subunits made up of small facets in hexagonal array, with a lattice spacing of ~ 90 Å. The main point for this paper is that this synapse, which transmits electrically, is characterized by numerous close contacts between presynaptic and postsynaptic membranes in which the gap between the membranes is obliterated. It should be noted that other synapses specialized for electrical transmission show similar synaptic-cleft occlusions. Martin and Pilar (1963) showed that the calyciform endings on certain nerve cells in the chick ciliary ganglion transmit by an electrical mechanism, and Takahashi and Hama (1965) found the expected regions of synaptic-cleft occlusion. Pappas and Bennett (1966) again found a clearcut association of tight junctions with electrotonic coupling between giant pacemaker neurons in certain fish brains.

In the early days of application of permanganate fixation to cells and tissues, I noted tight junctions between adjacent mouse intestinal epithelial cells, similar to those seen in the electrical synapses, as well as close contacts between smooth

muscle cells (Robertson, 1959). Furthermore, Sjöstrand and Andersson (1954) noted extremely close contacts between adjacent membranes in cardiac muscle. Farquhar and Palade 1964) conducted an extensive survey of epithelial cell unctions and found that close contacts, usually called 'tight junctions," occurred extensively in epithelial tissues. Subsequently, Revel and Karnovsky (1967) studied such tight junctions by using a variant of the lanthanum staining method originated by Doggenweiler and Frenk (1965), and found the same kind of hexagonal array of subunits that had been demonstrated in the synaptic disk of the club endings. Even the repeat period of the subunits in their material was the same. Loewenstein (1966) demonstrated that many kinds of epithelia are characterized by electrotonic coupling between adjacent cells associated either with tight junctions or septate desmosomes.

As a result of all these lines of evidence, it is accepted that the tight junction is a region in which electrical coupling might be mediated. However, it also seemed likely that electrotonic coupling could also be mediated by septate desmosomes. The general concept has arisen that an essential result of electrotonic coupling is the prevention of lateral leakage of current. This could be accomplished by making the membranes come very close together or by interposing some element, such as the dense material of the septate desmosomes, to impede lateral current leakage. It is interesting to note here that nodes of Ranvier apparently use both of these methods in achieving saltatory conduction, because in some nodes there is a complete occlusion of the cleft between the Schwann cell membrane and the axonal membrane in the juxtaterminal myelinated region (Robertson, 1954), but in other nodes (Doggenweiler and Heuser, 1967; Hirano and Dembitzer, 1967) septate desmosomes that repetitively encircle the axons apparently serve the same purpose of limiting longitudinal leakage of current along the cleft between the axon and the Schwann cell from the internodal regions to the nodes. This kind of mechanism appears to be important in insuring current flow through the nodal membrane to satisfy the conditions for saltatory conduction.

Before leaving the subject of electrotonic coupling via tight junctions, I should mention that electrophysiological evidence of electrotonic coupling between cardiac muscle cells via tight junctions was soon forthcoming (Dewey and Barr, 1962, 1964). Recently McNutt and Weinstein (1969), Kreutziger (1968a, 1968b), Somer and Steere (1969), and Somer and Johnson (1970) have studied tight junctions in cardiac muscle tissue by means of the freeze-fracture technique. They have produced evidence that there is, in the central plane of the nexus, a regular hexagonal array of subunits with a center-to-center spacing of about 90 to 100 Å. McNutt and Weinstein regarded each subunit as a "contact cylinder" about 60 Å high by 60 Å in diameter.

The cylindrical particles are separated from one another by 20 to 30 Å of open space and have a center-to-center spacing of 90 Å. There is a 40-Å-deep central depression in each subunit. Opposite the contact cylinders on the cytoplasmic surface of the membrane are seen globular subunits in hexagonal array, with each subunit ~ 40 Å high and spaced with a center-to-center distance of 90 Å. These authors also believe that each of the subunits has a central pore about 20 to 25 Å in diameter and that these juxtacytoplasmic subunits each lie opposite a central cylinder. There is also evidence (Kreutziger, 1968b) of a similar subunit array in tight junctions or nexuses in mouse liver. Outside the region of tight junctions in cardiac muscle, Somer and Johnson (1970) have evidence that there is a smaller hexagonal array with a spacing of ~ 60 Å within the membranes, but it is not yet clear whether it is in the inner leaflet or the interior. However, their findings are compatible with the notion that some sort of special apparatus is added to the underlying unit membrane in regions of tight junctions that are designed for electrotonic coupling.

GENERAL SYNAPTOLOGY In 1959, Gray applied a vigorous staining method (OsO4 followed by ethanolic PTA) to vertebrate cerebral-cortical synapses, with resultant new findings. The method produced very heavy staining of certain elements, which permitted him to define two types of synapses. Both show presynaptic clusters of vesicles and membrane specializations manifested by dense material built up on both the presynaptic and postsynaptic membranes. In Type 1 there is a widening of the synaptic cleft to about 300 Å and there is a dense band about 100 Å thick in the cleft, but placed asymmetrically, being closer to the postsynaptic than to the presynaptic membrane. Gray observed, immediately beneath the postsynaptic membrane, a dense band of amorphous material, several hundred angstrom units wide, which appeared presynaptically as clumps spaced at intervals of a few hundred angstrom units. The synapse was found to occupy most of the area of synaptic contact. Gray regarded this particular morphological configuration as being the actual site of synaptic transmission. Type 1 appears characteristically in dendritic spines, whereas Type 2 is found more often on cell bodies. Here the regions of membrane specialization are less extensive, occupying only about 0.25μ . The presynaptic and postsynaptic specializations, as well as the clusters of synaptic vesicles, are, however, somewhat similar.

Whittaker and Gray (1962) conducted a combined electron microscope and biochemical study of certain fractions obtained from brain homogenates and showed that they contained predominantly synaptic boutons. Whittaker (1959) and, independently, De Robertis et al. (1961) showed that the boutons contain synaptic vesicles, which in turn contain ACh, thus lending support to the notion of quantal release by a mechanism of vesicle fusion with the presynaptic membrane, as mentioned above. Evidence in recent work reported by Whittaker (this volume) suggests that the acetylcholine in the nerve endings exists in two pools. One of these is in the vesicles, and the other is in the axoplasm of the ending. Present evidence seems to suggest that the ACh released during activity is from the free pool rather than from the vesicles. This finding could be interpreted to indicate that the synaptic vesicles are a repository for reserve ACh, but the ACh secreted as a neurotransmitter is that which is newly synthesized and found in the axoplasm of the ending. This topic is extremely controversial at present, and the above conclusion is in direct contradiction to the currently accepted quantal-release hypothesis, whereby the ACh is released from the vesicles by a mechanism of exocytosis.

The synapse of the retinal-rod receptor cell and the bipolar cell in vertebrate retina was one of the earliest synapses studied by electron microscopy (Sjöstrand, 1961), but it is not dealt with here beyond mention of certain special features of retinal synapses noted by Kidd (1962), who found many of the kinds of synaptic specialization described by Gray. In addition, Kidd frequently found in the pigeon retina what appeared to be three terminal axons in synaptic relationship with one another, as indicated in the diagram of Figure 8. A synaptic membrane specialization resembling the Gray Type 1 is seen between P_1 and P_2 ; P_2 , in turn, contains a similar specialization in relationship to P3. Kidd postulated that this relationship provided a morphological basis for presynaptic inhibition. An impulse arriving in P1 would activate P2 so as to diminish its response to an incoming impulse and hence decrease its effect on P₃. Normally, P₂ would fire P₃, but, because of the influence of P1, it might not. Eccles (1964) predicted that

FIGURE 8 Diagram adapted from Kidd (1962) showing three (P_1-P_3) boutons, each containing clusters of synaptic vesicles related by two membrane specializations like the one seen in Gray Type 1 synapses. P₃ is related to a dendrite with a similar specialization.

there should be such structures, particularly in spinal cord, and Gray (1962), as well as Kidd (1962), studied the matter further and indeed found them. Gray made the point that they have been found in every place where physiological evidence indicates presynaptic inhibition should occur. However, it is interesting that, although Kidd found large numbers of these structures in the pigeon retina, he found them infrequently—only four times, in fact—in analogous parts of the retina of the cat. In any case, this particular relationship of synaptic specializations has been taken by many as indicative of presynaptic inhibition.

Excitatory and inhibitory synapses

The recognition of excitatory and inhibitory synaptic endings by specific morphological features is obviously of great importance. The first clearcut claim for the morphological differentiation of excitatory and inhibitory endings was made by Uchizono (1965). He claimed that endings on Purkinje cells, which Eccles had designated physiologically as inhibitory, characteristically contained flattened and relatively small vesicles, and he noted that other types of endings thought to be excitatory had relatively large spherical vesicles. He associated the latter with the Gray Type 1 ending and the former with the Gray Type 2 ending.

In 1966, Bodian published micrographs of spinal motor neurons of the monkey that showed two distinct types of nerve endings; one of these contained spherical vesicles ~ 200 to 400 Å in diameter ("S" type); another contained vesicles of ~ 100 to 200 by 300 to 600 Å ("F" type). He interpreted the latter as representing flattened vesicles. He did not claim to be able to distinguish if one or the other of these types of endings might be excitatory or inhibitory, but concluded that he might be seeing a morphological feature that would serve to differentiate excitatory and inhibitory endings.

In 1967, Uchizono reported a study of the crayfish stretch receptor in which excitatory and inhibitory endings could be clearly differentiated. He obtained micrographs of the inhibitory endings on the dendrites of the receptor cell and found that they contained vesicles of the small, flattened type. He found that the excitatory endings on the muscle fibers contained vesicles of the rather large spherical type. Uchizono also studied certain crab muscles which have a double innervation, one excitatory and one inhibitory, and found that some of these endings contained flattened vesicles and some spherical vesicles, again consistent with his hypothesis.

In 1967, Larramendi et al. conducted an extensive statistical study of glutaraldehyde-OsO₄-fixed mouse cerebellum in which they attempted to relate vesicle size and shape to age. Their findings supported Uchizono's conclusions and added the interesting point that synaptic vesicles tend to decrease in size with age.

It is too early, at this time, to state with certainty that a definite morphological basis for the differentiation of excitatory and inhibitory endings has been established. It appears reasonably certain, however, that different types of endings may be distinguished by the appearance of the synaptic vesicles after glutaraldehyde-OsO4 fixation. This is purely an empirical matter, and already some contradictory elements are beginning to appear. For instance, it is now recognized that some of the synaptic vesicles are extremely labile. Thus it has been found that some vesicles may become flattened after glutaraldehyde fixation if they are placed in a buffer for as short a time as 30 minutes. If the buffer wash is omitted, they may appear largely spherical. It is thus necessary to define very accurately the conditions of preparation, and to the extent that these have not yet been clearly worked out, the differentiation of excitatory and inhibitory endings on the basis of vesicular size and shape remains somewhat uncertain. It is to be hoped that, within the near future, it will be possible to make clearcut distinctions of excitatory and inhibitory endings based on such distinctive morphological features as the shape and size of synaptic vesicles. Mitochondrial characteristics may also play a part. Until more work has been done, it seems fair to say that the differentiation of excitatory and inhibitory endings remains uncertain.

Juxtamembranal specializations

In the above discussion, several kinds of juxtamembranal specializations that take place in synaptic regions have been mentioned. I shall now turn to some more extreme specializations that have been found in synaptic endings. These are closely related either to the presynaptic membrane or to the postsynaptic membrane. For the most part, these specializations are simply amorphous dense bodies of various shapes, sizes, positions, and aggregations.

One of the first such specializations described was presented by Taxi in 1965 in his studies of superior cervical sympathetic-ganglion synapses. He described several irregular rows of dense bodies 200 to 300 Å in diameter, beginning about 250 to 600 Å away from the postsynaptic membrane, and of decreasing length proceeding successively away from the postsynaptic membrane. In 1966, Milhaud and Pappas, in a study of the habenula of the cat, noted, in about one third of the synapses they studied, peculiar arrays of subjunctional dense bodies rather like those seen by Taxi but in a regular hexagonal array.

In 1967, Akert et al. described the fine structure of a peculiar kind of synapse found in the subformical organ of the cat. This has subjunctional dense bodies about 200 to 300 Å in diameter, about 500 Å apart in a hexagonal array,

placed in a row about 500 Å from the postsynaptic membrane. These synapses are characterized by presynaptic densities and clusters of vesicles much like those described by Gray.

Recently Akert and Sandri (1968) applied a zinc-iodide osmic method to a study of the crest synapses, with some interesting new results. This procedure impregnates certain synaptic vesicles with dense material. At first it was thought that this might be specific for cholinergic endings, because the reaction was prominent in motor end plates, but it was soon found that the impregnation was not specific. Nevertheless, it is certainly striking that some synaptic vesicles are impregnated and some in the same block are not. However, Akert and Sandri (1968) and Pfenninger et al. (1969) used this technique profitably with a considerable clarification of the nature of presynaptic and postsynaptic dense bodies. Figure 9 is a diagram taken from Pfenninger et al. (1969) summarizing their findings on the presynaptic densities.

FIGURE 9 Diagram of axon terminal taken from Pfenninger et al. (1969). *Abbreviations:* cv, clear vesicle; dv, dense core vesicle; dp, dense projection. See text for further details.

They now visualize the presynaptic dense projections as being each about 550 Å in diameter, 600 Å high, and 800 Å apart in a regular hexagonal array. They believe the dense projections are interconnected by strands of dense material, as indicated in the diagram. They note that there is approximately enough space to fit one synaptic vesicle into the open region between the dense bodies. These workers have also described a considerable enhancement of the postsynaptic dense material after the zinc-iodide procedure, and also an enhancement of the dense material in the cleft between the presynaptic and postsynaptic membranes. They have observed that this material is split into two thin, dense layers in some preparations. They favor the concept that the presynaptic dense bodies in some way guide the presynaptic vesicles to the appropriate place on the presynaptic membrane, where their contents are released. Gray (1966) made a similar proposal, but regarded the dense bodies as sites of attachment.

Moor et al. (1969) have recently begun studies on freezeetched preparations of brain tissue, and are elucidating the structure of synapses by the use of this method. In boutons they saw irregularly spaced dimples that might very well represent caveolae. Interestingly, these appear to be distributed more-or-less randomly over the whole surface of the boutons rather than concentrated in the region of membrane specialization, as might be expected if the caveolae do, indeed, represent regions in which synaptic vesicles are caught and where they empty their contents after having fused with the presynaptic membrane, as would be called for by the quantal-release exocytosis hypothesis. Of particular interest in these micrographs is the demonstration that the synaptic vesicles are discrete isolated bodies, as commonly believed. This provides a powerful new piece of evidence attesting to the nature of the vesicles.

In conclusion, I wish to discuss speculatively whether the vesicle really is related to quantal release and "exocytosis," because I believe this to be a fundamental problem. As mentioned above, I regarded this concept as suspect from the very beginning. The fact that the vesicle membrane and the synaptosome membrane are chemically distinct makes the simple exocytosis concept difficult to accept. Further, the evidence that ACh exists free in the cytoplasm of the synaptosome and that this is the material that is first released casts further doubt on the concept. On present evidence, it would appear at least possible that the vesicles may, in fact, represent a storage site for ACh and that the release occurs by some other mechanism. It is not at all difficult to imagine some sort of molecular gate, distributed in numbers over the presynaptic membrane, that, in response to an electrical depolarization, would open just enough to let a reasonably constant number of acetylcholine molecules pass through to the synaptic cleft before closing. Such a mechanism would account for quantal release and for the miniature end-plate potentials if the gates were assumed to open randomly with a certain low frequency without arrival of an impulse. The ACh in the vesicles would then be called upon if the immediate store in the axoplasm were exhausted. This viewpoint represents a radical departure from the apparently well-established central dogma of synaptology, but it has the virtue of getting around some of the difficulties of release by exocytosis.

If it is necessary to retain the concept of quantal release from the vesicles by some variant of the original idea, I

wish to propose a tentative mechanism that could work without excessive destruction of membrane or intermixing of vesicular and axonal membrane substance. It may possibly be true that the synaptic vesicles are indeed derived from an interconnected tubular system that is branched many times with only a limited number of connecting points with the presynaptic membrane. Arrival of a membrane depolarization might cause this system to contract suddenly, perhaps by means of a spread of a protein conformation change over the membrane surface, causing it to expel the globular aggregates of acetylcholine in packets, as required by the quantal-release theory. (For a contractile model of transmitter release, see Poisner, 1970.) The necks between vesicles and the neck connecting to the synaptic membrane would remain patent, according to this view, between discharges and, as the tubules became recharged, one might expect ACh to become aggregated into pools by a microperistaltic action produced by membrane contraction. This would be further expected to lead to occasional random expulsion of the aggregated packets at the regions where the system connects with the presynaptic membrane. There are two ways that one could rationalize such a system with the observed facts. The simplest is to assume that the system is highly unstable, requires energy to be maintained, and breaks down into isolated vesicles at the slightest insult.

This is not an unreasonable assumption, because many such membrane systems now are known to break up during fixation into vesicles. The myelin sheath of the prawn is a good case in point; the slightest variation in fixation techniques from the optimal ones results in sheaths made of aggregates of vesicles (Heuser and Doggenweiler, 1966). The "T-system" of the skeletal muscle fiber is another example (Franzini-Armstrong and Porter, 1964). In 1956 I postulated that tubular membranous elements reported in lizard muscle (Robertson, 1956a) constituted a transverse membranous system connecting with the surface of the muscle fiber and explaining Hill's (1949) paradox. These connections were, however, not observed for many years, simply because fixation methods good enough to preserve them had not been developed. Other cases could be cited in which the introduction of new methods has resulted in the demonstration of tubular membranous continuity, whereas only vesicular systems were seen with older methods. The failure to demonstrate such connections initially in freeze-fracture preparations does cause some pause in this argument. However, the technique is plagued by its own artifacts and interpretative problems, and its results should not be taken too literally. Nevertheless, there does seem to be some hope that the freeze-fracture technique may settle this long-standing problem.

There is one additional way in which a mechanism may be proposed that would account for all the observed facts. To be sure, it has the drawback of being complex. I base it on some studies by Schneider (1960) on contractile vacuoles in certain Protozoa. It has been found that the expulsion of water from contractile vacuoles occurs from the general kind of interconnected tubular system that is postulated above. If fixed at the proper stage in formation and filling before discharge, the interconnected tubular system can be seen clearly. However, if the system is fixed immediately after discharge, only a single channel surrounded by numerous isolated short tubules can be seen. We might draw an analogy with this system, and say that, in preparation for discharge, synaptic vesicles line up in rows and fuse with one another to make an effectively interconnected tubular system, which, in turn, is fused with the surface membrane; in this state, the system would then be, so to speak, "cocked" and ready to fire. The arrival of the nerve impulse would cause an immediate discharge of the contents of the system, which would be followed by an immediate breakup of the system into isolated vesicles. Figure 10 is designed to illustrate this idea, the advantage of which is that no vesicular membrane would become a permanent part of the presynaptic membrane. It would also account both for the

FIGURE 10 Diagram of a synaptic bouton, showing how synaptic vesicles might originate by breakdown of an interconnected tubular system. The dotted lines represent the two states of the system.

presence of isolated vesicles in the presynaptic terminals most of the time and for the findings in freeze-etch preparations. It would only be during the cocking of the system that the vesicles would be interconnected, although the external connections might be somewhat more persistent. It may be assumed that the cocking is a very fast event, taking place with the arrival of the nerve impulse by some kind of electrophoretic effect and lasting only as long as the membrane depolarization persisted. Thus, successful display of the cocked system would be difficult. This mechanism is admittedly complex, but really no more so than the exocytosis mechanism. All it really adds is a plausible way to reverse the membrane flow quickly. On balance, even though it does not explain the presence of caveolae in the presynaptic membrane, I would say that the membrane gating mechanism in which the vesicle is only a storage vehicle is more likely.

65 Correlating Structure and Function of Synaptic Ultrastructure

F. E. BLOOM

THE BASIC DETAILS of synaptic fine structure have been known for more than 15 years (Palay, 1956, 1958). Although scores of major and minor variations on the basic theme have been described, the functional importance of the relatively few cellular organelles apparent at the synapse has scarcely been elucidated. Many recent chemical studies (Appel et al., 1969; Mahler, 1969; and Barondes, 1968, an earlier paper in this volume) have indicated that isolated synaptic endings may be able to restructure some of their macromolecular protein constituents. Consequently, those persons interested in testing the "code of life" dogma (DNA to RNA to protein to function) as a mechanism for the learning or memory trace have again turned to fine structure, where the seductively high resolution of the electron microscope offers the promise of equating structure with function. In this essay, I attempt to explore the factual constraints of synaptic fine structure, re-emphasizing some of the topics described by Dr. Robertson in the previous chapter. From these basic constraints, I have tried to indicate the most obvious types of microstructural changes compatible with induced subcellular neuroplasticity, emphasizing proposals that can best be subjected to experimental testing. From these constraints and proposals, we can each judge the width of the "synapse gap" as one of the weak links in molecular neurobiology. Even the freshest novitiate to the neurosciences will realize, however, that the resolution of the mechanics and molecular potentialities of the synapse is unlikely to come from fine-structural experiments alone.

THE BASIC STRUCTURAL CONSTRAINTS The synapse is truly a "mixed bag." To the physiologists, the synapse is the functional transducer that converts the electrical activity of the all-or-none action potential of the axon into chemical secretion of a transmitter, thereby producing electrical activity in the postsynaptic cell. Most electron microscopists would apply the term synapse when two morphological components are present: (1) a specialized interneuronal contact zone between nerve terminals and dendrites, cell bodies, or other postsynaptic elements, that appears morphologically different from all other intermembranous conjunctions; and (2) the presynaptic accumulation of synaptic vesicles with partial or complete exclusion of axonal microtubules (Figure 1). The visualization of both these essential structural synaptic features depends on the type of fixation used for tissue preparation.

Synaptic vesicles

In general, when such fixatives as osmium or permanganate are used to heighten the opacity of the membranous components, the most striking feature of the synapse is the large number of synaptic vesicles. The first question to be asked, then, is whether the size, shape, electron opacity, and intraaxonal distribution of vesicles can be related to synaptic functioning. Let us note, in passing, that, although the shape and configuration of synaptic vesicles seen in electron micrographs may not represent their native conformation in the brain prior to examination, no methods for examining native vesicles *in situ* have yet been devised.

Furthermore, some basic clarification is needed as to the origin of synaptic vesicles within the nerve terminal. Akert and his group have recently published freeze-etch electron micrographs (Akert et al., 1969) in which they have observed what appear to be pinocytotic invaginations of the axonal membrane. These invaginations do not occur at the area of the synaptic specialization. If synaptic vesicles were to form by budding from the axonal membrane (Westrum, 1965), their lipid composition must also change in the process, because Whittaker (1966) has shown that the lipid composition of synaptic vesicles is different from that of synaptosomal membrane. Where else, then, might the synaptic vesicles arise? The only other known source of "unit plasma membrane" in the terminal is axonal mitochondria. There is no evidence that vesicles bud from mitochondria, so might they be assembled at the mitochondrion from mobile proteolipid subunits? Or, despite the rarity of their sighting within axons, did all these vesicles pass to the terminals only by axoplasmic flow from the soma? We simply do not know!

F. E. BLOOM Laboratory of Neuropharmacology, Division of Special Mental Health Research, National Institute of Mental Health, Saint Elizabeth's Hospital, Washington, D. C.

FIGURE 1 Neuropil in the molecular layer of the rat cerebellar cortex, illustrating two axodendritic contacts that exhibit presynaptic spherical, electron-lucent synaptic vesicles, and distinctly specialized zones of contact. An axodendritic contact with presynaptic vesicles, but no specialized zone of

contact, is seen at the lower right. Note that, for the contact at upper left, the entire contacting surfaces between the axon and dendrite are specialized; for the larger contact at upper right center, only a portion of the apposing surfaces are morphologically specialized. Magnification, $\times 65,000$.

Perhaps the best connection between synaptic vesicles and synaptic function is derived from brain homogenate studies, which have shown that the nerve endings (or the vesicle fractions subsequently derived from nerve endings) are the richest sources of suspected transmitter substances (see both Whittaker and Iversen, this volume). Because the peripheral autonomic transmitters, acetylcholine (ACh) and norepinephrine (NE), can be related to particular nerve endings within the autonomic nervous system (see review by Eränkö, 1967), analogous cytochemical methods have been applied to the central nervous system for purposes of identifying nerve endings on the basis of their neurotransmitters. These studies can best be reviewed by classifying vesicles on the basis of their electron opacity in routinely prepared electron micrographs (Figure 2). ELECTRON-LUCENT SYNAPTIC VESICLES The majority of synaptic vesicles seen in central nerve endings are electronlucent (that is, of low electron density) and measure between 200 and 600 Å in diameter. This type of synaptic vesicle abounds in the classically cholinergic neuromuscular junction; it also occurs in isolated nerve-ending particle fractions of brain homogenates rich in ACh (see Whittaker, this volume). It is not clear, however, whether this basic vesicle morphology is indicative of nerve endings containing ACh or is simply the basic model of synaptic vesicles. Electron-lucent synaptic vesicles have also been described in nerve endings found in homogenate fractions not containing large amounts of ACh, and presumably, then, they must also serve to contain such transmitters as amino acids and the large population of as-yet-unspecified synaptic

FIGURE 2 Illustration of the variations among sizes, shapes, and electron-opacity of contents for the various central and peripheral synaptic vesicles and two of the transmitters to which they may be related. The upper two rows indicate the electron-lucent vesicles, most commonly related to acetylcholine content (ACh), as at the neuromuscular junction. The lower two rows illustrate the varia-

tions among the electron-opaque synaptic vesicles related to content of monoamines, such as norepinephrine (NE) and serotonin (5-HT). The reference mark indicates 1000 Å. At right are noted some of the factors that may relate to the variations in vesicle morphology.

transmitter agents. We may presume that only a portion of the electron-lucent synaptic vesicles will be shown to contain ACh, for which no cytochemical test has yet been conclusively demonstrated. The zinc-iodide-osmium method of Akert (Akert and Sandri, 1968) and the metallic impregnation studies of Howard (personal communication) suggest the emergence of such a method. In its stead, enzyme histochemical localizations for cholinesterase, acetylcholinesterase, and cholineacetyltransferase have been used to specify cholinergic content at the vesicle level (see Koelle, 1969; Karczmar, 1969).

Electron-lucent synaptic vesicles have also been subclassified on the basis of their shape. Although the majority are spherical, certain nerve terminals, particularly when fixed by formalin perfusion techniques (Uchizono, 1965; Bodian, 1966a, 1966b), contain smaller, pleomorphic vesicles. The latter, typically flat synaptic vesicles, were functionally related to "inhibition" on the basis of their appearance in certain cerebellar-cortex nerve terminals, the functional characteristics of which are specifiable (Eccles et al., 1967), and on the basis of a comparison of the development of inhibition with the appearance of flat vesicles in their nerve terminals (Bodian, 1966b).

This area is one of the few in electron microscopy of brain in which quantitative measurements have been made on a series of material large enough to provide certain statistically significant correlations. Lenn and Reese (1966) analyzed the ventral cochlear nucleus of several rodents and interpreted their vesicle measurements to indicate that the nerve endings containing smaller synaptic vesicles were associated with the inhibitory afferent terminals of higher auditory centers. Larramendi et al. (1967) have made large numbers of measurements on synaptic vesicles in rodent cerebellar cortex to evaluate the conclusion of Uchizono (1965) that inhibitory nerve terminals, particularly those basket-cell terminals ending upon Purkinje cell bodies, exhibited small, oval, synaptic vesicles, whereas excitatory endings, such as those of parallel fiber and mossy fiber, have vesicles that are larger and more spherical in shape (Figure 1). The interesting conclusion reached by Larramendi and his group was that the size of the vesicle tended to decrease with development, and that those nerve terminals whose general functional classification is inhibitory were more likely to have smaller synaptic vesicles than were those found in cerebellar cortical nerve terminals thought to be excitatory (Eccles et al., 1967). The difference in vesicle size could be related to the rate at which the vesicles are utilized (metabolically consumed or emptied for refilling): large synaptic vesicles in less mature nerve terminals might indicate a faster utilization than do the smaller vesicles, which have survived longer (Larramendi et al., 1967).

The functional classification of electron-lucent vesicles based on criteria of shape or size has not yet been chemically related to specific transmitter agents. In my own experience with autonomic nerve endings of the rat vas deferens, which is generally considered to be exclusively adrenergic, I have observed that vesicles that are typically spherical when they contain demonstrable electron-granular cores can become flat when the catecholamine content has been pharmacologically depleted. Central nerve endings thought to contain NE have also been observed to contain either round or pleomorphic vesicles (Descarries, personal communication). Thus, the size and shape of the vesicle could be related to: (1) function; (2) types of transmitter content; (3) amount or state of transmitter content; or (4) age of the vesicle within the nerve terminal. These underlying factors could predispose certain vesicles to alter their shape during fixation (Walberg, 1966), although the pleomorphic vesicles can be observed with several different methods of fixation (see Fukami, 1969).

ELECTRON-OPAQUE SYNAPTIC VESICLES There are two populations of electron-opaque synaptic vesicles, one 400– 600 Å in diameter, the other 800–1200 Å (Figure 2; Grillo and Palay, 1962). To the eyes of some, these vesicles represent diminutive declensions of the adrenal chromaffin granule, which, in turn, belongs to the general line of secretory particles such as those containing zymogens (Palade et al., 1961) or antidiuretic hormones (ADH) (Bargmann, 1966). Fine-structural analyses of the peripheral sympathetic nervous system have provided many data on the identification of the smaller synaptic vesicles that exhibit electron-granular content (Figure 3A) as the storage organelles of catecholamines. This identification is based on four types of data. First, the small granular vesicles have been observed in virtually every sympathetically innervated structure examined, provided the fixation has been adjusted to the tissue (see reviews by Grillo, 1966; Bloom and Giarman, 1968a; Tranzer et al., 1969; Jaim-Etcheverry and Zieher, 1969). The vesicles become even more opaque after the nerves have taken up substituted catecholamines such as 5-OH dopamine (Tranzer and Thoenen, 1967) and alphamethyl NE (Bondareff, 1966; Hökfelt, 1968). Second, the granular contents of these granular vesicles 400-600 Å in diameter can be correlated with the intensity of the fluorescence-histochemical or biochemical estimation of catecholamines after pharmacological depletion or enhancement (Van Orden et al., 1966, 1967a). Third, by the use of

FIGURE 3 A. Two perivascular nerve terminals from the pineal of the rat, after fixation with glutaraldehyde and standard exposure to osmium tetroxide. These nerves are filled with vesicles of the small granular type (SGV), which in this normal animal constitute about 60–80 per cent of the vesicles seen. Modified from Bloom and Giarman, 1969. Magnification, \times 50,000. B. Two nerve terminals from the

paraventricular hypothalamus of the rat after glutaraldehyde perfusion and exposure to osmium tetroxide at 60°C for 30 minutes. The spherical synaptic vesicles in the lower ending are filled with electron-opaque osmiophilic precipitates, while the smaller, pleomorphic vesicles in the upper terminal are electronlucent. (Modified from Bloom and Aghajanian, 1968c.) Magnification, $\times 50,000$. electron-microscope autoradiography, radioactivity can be shown to concentrate in nerve endings that exhibit these small granular vesicles (Wolfe et al., 1962). Fourth, the nerves that exhibit the small granular vesicles degenerate on destruction of the postganglionic sympathetic nerve trunks (Pellegrino de Iraldi et al., 1965; Van Orden et al., 1967b). A more recent approach to the localization and understanding of granular vesicles has been the use of 6-hydroxydopamine (6-HDM) as a specific toxin causing local nerve-ending degeneration among various types of catecholamine-containing nerve endings in the periphery (Tranzer and Thoenen, 1968). However, the specificity and precise pathogenesis of the drug effects on fine structure still require additional data.

With this rather compatible story at hand for the periph-

eral nervous system, it was natural to apply the methods to the central nervous system (CNS) in an attempt to identify the catecholamine-containing nerve endings there. Until recently, however, small granular vesicles were not visible within the CNS, and attention was focused on the large granular vesicles (LGV) (Figure 4) (see Bloom and Aghajanian, 1968a; Bloom and Giarman, 1968a). The LGV could be seen to exhibit variable amounts of electron-granular content which was similar, although not identical, to the granularity seen in the small granular vesicles (see Grillo and Palay, 1962). The granularity of the small vesicles is typically solid and homogeneous, although the relative filling of the vesicle interior varies widely. Possibly this variation is related to species, tissues, and relative amine content, but it appears most closely related to fixation. The

FIGURE 4 Autoradiograph of nerve terminals in the pontine raphé nucleus of the rat brainstem. Tissue was prepared two hours after intracisternal labeling with 0.8 micrograms of ³H-serotonin, and otherwise routinely prepared by the methods of Aghajanian and Bloom (1967a, 1967b). The

nerve terminal with two large silver grains is making an axodendritic contact with a small dendritic spine; this terminal has many large granular vesicles and even more numerous electronlucent vesicles. (From Bloom and Couch, unpublished.) Magnification, ×65,000. granularity of the large vesicles varies mainly in electronopacity, the interior appearing either fibrillar or wispy, but usually filling most of the vesicle interior. The LGV were found in brain-homogenate fractions rich in NE nerve endings (de Robertis et al., 1965), and early evaluation of the effects of catecholamine-depleting drugs suggested that the granular content could be depleted (Pellegrino de Iraldi et al., 1963; Bak, 1965, 1967; Hashimoto et al., 1965; Ishii et al., 1965; Matsuoka et al., 1965; Shimizu and Ishii, 1964). The LGV have been observed in the majority of nerve processes over which autoradiographic grains are found after labeling endogeneous brain stores by intraventricularly injected 3H norepinephrine (Aghajanian and Bloom, 1966, 1967b; Lenn, 1967; Descarries and Droz, 1968) or ³H serotonin (5-HT) (Figure 4; Aghajanian and Bloom, 1967a). In studies utilizing lesions to cause degeneration of specific catecholamine- or 5-HT-containing nerve pathways, those nerve endings that degenerate can also be shown to exhibit LGV (Aghajanian et al., 1969; Raisman, 1969a). Furthermore, the LGV which have been seen in electron micrographs specifically correlate with selective fluorescence-histochemical examination of the hypothalamus (Eneström and Svalander, 1967).

However, other combined light and electron-microscope surveys (Lenn, 1965; Fuxe et al., 1965, 1966) indicated that the LGV could not be the only storage organelles of brain NE. When the large granular vesicles were quantified for several regions of rat brain and the values were compared with the reported regional brain content of catecholamine and 5-HT by either biochemical or fluorescencehistochemical measurement, a correlation was found between the total percentage of nerve endings containing large granular vesicles and the combined content of NE and 5-HT (Bloom and Aghajanian, 1968a). The electron-opacity of the content of the LGV, however, did not vary in magnitude with the expected change in the monoamine level when brain monoamine content was depleted or enhanced pharmacologically.

All the above data on LGV in the brain could be interpreted to mean that such vesicles are but one subcellular signature that indicate nerve endings able to store monoamines. They do not indicate that the LGV are the storage site of the monoamine; in fact, in virtually all the nerve terminals that exhibit LGV, large numbers of spherical electron-lucent synaptic vesicles can also be seen. Furthermore, LGV are also seen in autonomic terminals regarded as classically "cholinergic" (Taxi, 1961; Grillo, 1966; Bloom and Barrnett, 1966), although they differ with respect to loading by 5-OH dopamine (Tranzer et al., 1969).

Although many aspects of both central and peripheral LGV remain to be solved, their significance to transmitter storage has become more remote since the successful application of permanganate fixation. When potassium permanganate is used as the fixative on either fresh tissue blocks (Richardson, 1966) or thin slices of brain tissue incubated in NE, 5-HT, or alphamethyl NE (Hökfelt, 1967, 1968), synaptic vesicles in those regions of the brain rich in monoamines can be shown to contain small granular synaptic vesicles (SGV). Hökfelt (1967, 1968; Hökfelt and Jonsson, 1968) has shown, in an extensive series of experiments, that brain slices of caudate nucleus incubated in vitro in solutions of NE (1–10 micrograms per milliliter) exhibit the highest frequency of SGV in the nerve terminals. The same SGV can be seen in unincubated sections of hypothalamus and locus coeruleus, although the frequency is less. If the slices are taken from the brain of animals pretreated with reserpine to block storage of amines, no SGV are seen after subsequent incubation and fixation.

Depletion experiments have been shown to decrease the frequency with which small granular vesicles can be seen in brain structures after permanganate fixation (Hökfelt, 1968), but the experiment is difficult to perform because the fixation is variable and large sampling is not always possible; furthermore, the reproducibility of the fixation appears to vary from poor to adequate preservation. No autoradiographic studies have yet been performed to confirm that the permanganate granular vesicles are equivalent to catecholamine; those instances in which the experiments have been attempted (Hökfelt and Jonsson, 1968; Devine and Laverty, 1968; Bloom and Giarman, 1970) suggest that permanganate is not a superior preservative of radioactive catecholamine content. Furthermore, permanganate-fixed tissues, despite their equivocal retention of radioactive norepinephrine, fail to exhibit autoradiographic activity (Bloom and Giarman, 1970; Taxi, personal communication; Descarries and Droz, personal communication). Whether the failure is due to some oxidative breakdown of the NE isotope (Harrison et al., 1968) or to some chemographic reaction between the tissue and the emulsion, the results of this critical experiment are needed for complete interpretation of the small granular vesicle revealed in the brain with permanganate fixation.

Similar SGV can also be made to appear in electron micrographs by exposing glutaraldehyde-fixed brain to osmium tetroxide at elevated temperatures (Figure 3B). The question then arises as to whether the electron opacity of these granular vesicles represents catecholamine content either qualitatively or quantitatively. Attempts to correlate the "hot osmium" SGV with catecholamine content have so far been unsuccessful (Bloom and Aghajanian, 1968c), because both drug-depletion studies and autoradiographic studies fail to confirm that the granularities are associated with norepinephrine content. If the granular content of the small vesicles seen in the brain after permanganate or hot osmium could be associated with norepinephrine storage by autoradiographic or other independent cytochemical techniques, it would then be possible to utilize the granular material as a quantitative marker for functional experiments on monoamine-containing terminals. Methods will still be required to distinguish serotonin from NE-containing central nerve endings (see Jaim-Etcheverry and Zieher, 1968, 1970) and to establish a basic biological explanation for what distinguishes the reactivity of central small granular vesicles from the SGV of peripheral nerve endings.

On the other hand, the granular content of the large and small synaptic vesicles could be related to catecholamines indirectly, as a reflection of the chemical reactivity or avidity of the "matrix" within synaptic vesicles. What little evidence exists on the nature of adrenergic synapticvesicle matrixes suggests that they may contain a metallic cation, adenine nucleotides, and presumably some sort of phospholipoprotein (Colburn and Maas, 1965).

Synaptic specializations

The fine-structural specializations repeatedly observed at sites of interneuronal contacts represent the second major morphological feature of the synapse. These points of specialized contact have either been described in terms of their morphology (e.g., membranous thickening, intermembranous bridges, desmosomoid differentiation, synaptic membrane complex, open junction, and so forth) or simply named for their functional connotation as synapses. In osmium-fixed tissues (see Palay, 1956, 1967), this specialization is characterized by sites at which the plasma membranes of the apposing processes are parallel to each other and accentuated to variable degrees by electron-dense material that occurs in the adjacent presynaptic and postsynaptic cytoplasm and within the intersynaptic space (Figures 1, 2, 4, 5).

When properly sectioned, the intersynaptic cleft appears to be somewhat wider than other intercellular spaces (Kelly, 1967; Lenn and Reese, 1966). It must be remembered, however, that the intercellular spaces seen in commonly prepared electron micrographs of brain do not take into account the swelling and shrinkages that have occurred through the steps of fixation and dehydration (Van Harrevald et al., 1965).

When tissue is fixed with dilute permanganate (Figure 5A), the cytoplasmic electron densities at the specialized contact zone are poorly seen, and the zone is, therefore, characterized only by parallel membranes of the presynaptic and postsynaptic elements (see Gray and Guillery, 1966). When osmium-fixed material is stained with phosphotung-stic acid (PTA), the electron-dense material is particularly prominent (Figures 5B-D, 6A-C). Aghajanian and I (1966, 1967a, 1968b) have modified the PTA-staining procedure used by Gray (1959) on osmium-fixed blocks to study the nature of the paramembranous material found at specialized

interneuronal contacts. Our version of the staining procedure utilized glutaraldehyde-fixed nervous tissue stained in the block with ethanolic phosphotungstic acid (E-PTA). This procedure does not make membranes electron-opaque, but has the advantage that material stained with the electron-dense E-PTA is now selectively revealed (Figure 6A, B) in the same configuration as that described by Gray (Figure 5). This staining result clearly demonstrates that the electron-dense material is independent of the plasma membrane of the contacting neural processes. We have referred to the material that stains with E-PTA as "synaptic material," implying without proof that the sites at which it occurs are functional synapses. No other interneuronal surfaces, however, appear to be so specialized.

The organization of the synaptic material stained with E-PTA in different mammalian and vertebrate species and in different regions of the central and peripheral nervous system is, in general, similar. Four separate accumulations of material reactive with E-PTA can be consistently observed in thin sections that give a normal view of the contact site (Figure 6C). At the preterminal edge of the axoplasm of the terminal bouton, two to eight aggregates of moderately dense electron-opaque material project into the nerve terminal; these dense projections measure 300-500 Å in widest diameter and are separated from one another by 160-500 Å. Similar structures seen by Gray, who used PTA on osmium-fixed material (Gray, 1959), and by Akert and coworkers, who used bismuth iodide (BI) impregnation of glutaraldehyde-fixed material (Figure 5E) (Akert et al., 1969; Pfenninger et al., 1969), suggest that the dense projections occur in hexagonal arrays when viewed in frontal sections. These dense projections are not readily apparent in the neuropil of brains exposed to osmium tetroxide, where the material adjacent to the presynaptic membrane is seen only as dense granular patches varying in both size and shape (Figure 6B, C). Furthermore, their outline in osmiumfixed material is vague, irregular, and frequently amorphous, in part owing to the superimposition of the osmiumstained membrane of the synaptic vesicles.

A second element of the organized, dense, synaptic material is the highly dense electron-opaque band, 150–200 Å in thickness, situated just within the cytoplasm of the postsynaptic process. This element appears either as a continuous or as a discontinuous element equal in length to the opposing row of presynaptic dense projections.

The third element of synaptic material is an electronopaque line, 50–150 Å in width extending through what appears to be the center of the intercleft space. In our material fixed with glutaraldehyde and stained with E-PTA, the intercleft opaque line occasionally appeared to be perforated by small electron-lucent gaps. Material stained with BI (Akert et al., 1969; Pfenninger et al., 1969) exhibits an electron-lucent line down the center of the intercleft line,

FIGURE 5 Illustration of the variation in the electron-microscopic appearance of specialized interneuronal contacts after various types of fixative procedures (see text).

but this is not seen with the E-PTA preparation. This intrasynaptic element of the organized synaptic material can be compared with the thin fibrous residua occasionally seen as narrow lines or filaments within the synaptic cleft of osmium-fixed tissue.

Occasionally, a fourth element of synaptic specialization can be seen as fine wisps of electron-opaque material extending from the postsynaptic band into the cytoplasm of the postsynaptic neuron. The various synaptic staining procedures are summarized by the drawings in Figure 5.

Material reactive with E-PTA, and seemingly identical with the synaptic material, can also be visualized at myoneural junctions in several species. In this junction, presynaptic dense projections and continuous postjunctional bands lining the primary and secondary clefts of the junction are heavily stained. The "dendrodendritic junctions" (see both Rall and Shepherd in this volume) of the olfactory bulb of the rat also exhibit the polarized appearance of typical synaptic material. When the CNS of more primitive invertebrate nervous systems is examined, we have difficulty in finding distinct and clear accumulations of synaptic material that is equally specialized. The presumed osmium equivalent, however, can be seen in the CNS of squid (Castejón and Villegas, 1964) and octopus (Jones, 1969), insects (Smith, 1965; Boadle and Bloom, unpublished results), and, possibly, planaria (Best and Noel, 1969).

We have found that certain tissue elements, other than the synaptic material, exhibit affinity for the E-PTA stain (Bloom and Aghajanian, 1968b). In tissues of both nervous and non-nervous origin, the nucleoli and nuclei were stained, as were collagen, erythrocytes z bands in striated muscle, and the large granular synaptic vesicles (Bloom and Aghajanian, 1968a, 1968b; Jaim-Etcheverry and Zieher, in press). Sheridan and Barrnett (1969) have recently investigated the staining of nuclei, and their cytochemical investigations support our suggestion that the staining with E-PTA is the result of epsilon amino groups of basic amino acids present in macromolecular proteins or

FIGURE 6 A. Low-power electron micrograph of molecular layer of rat cerebellar cortex after glutaraldehyde fixation and staining with ethanolic phosphotungstic acid (E-PTA). Most prominently stained are the numerous specialized interneuronal junctions, characterized by the continuous postsynaptic density and the two to eight presynaptic dense projections. Vague paramembranous outlines, microtubules, and mitochondrial matrixes can be seen faintly in the background. (Modified from Bloom and Aghajanian, 1968b.) Magnification, $\times 30,000$. B, C. High-magnification comparison between specialized synaptic contact zones as seen after standard preparative techniques and heavy metal

staining of the thin section (B) and after E-PTA staining (C). Although little, if any, distinct material can be seen presynaptically in B, except for synaptic vesicles, the intersynaptic cleft and the immediate postsynaptic cytoplasm are filled with a fibrillar electron-opaque material. In C, the presynaptic dense projections, a somewhat faint intersynaptic line, and a prominent postsynaptic band are seen; the electron-opaque lines occupied by the unstained presynaptic and postsynaptic plasma membranes can be directly related to their osmium-opaque structures in B. Both B and C are from adjacent blocks of rat cerebellar cortex, perfused 14 days postnatally. Magnification, $\times 210,000$.

glycoproteins. Essentially, these data are based on the fact that proteolytic enzymes removed the material that stains with E-PTA (Bloom and Aghajanian, 1968b), whereas we could find no other cytochemical digestion methods that could eliminate the E-PTA staining property. E-PTA staining could also be prevented by acetylation of amino groups. In quantitative cytochemical reactions, Silverman

and Glick (1969) have recently provided data that confirm this explanation for PTA staining.

Similarly, proteolytic enzymes prevent the BI impregnation of specialized contacts, and in vitro tests indicate high affinity of BI for polylysine and polyarginine (Akert and Pfenninger, 1969).

The protein interpretation of the E-PTA staining differs

from that of Pease (1966), who has proposed that aqueous PTA, when used to stain sections of unfixed tissues dehydrated with various glycols, stains "polysaccharides." This polysaccharide staining is also reproduced by a modification of the periodic acid-Schiff stain, with silver as an electron-opaque marker for electron microscopy. With the use of this technique, polysaccharides can be stained in cell coats of the CNS, and this material appears to be somewhat thickened in areas identified as synaptic clefts (Rambourg and Leblond, 1967). In none of the studies by Rambourg and Leblond, however, do the presynaptic or postsynaptic components of the synaptic material stain, although they are regularly stained with E-PTA.

We may therefore assume, on the basis of these data, that a protein comprises the synaptic specialization and accounts for the electron-dense material in the cytoplasm of presynaptic and postsynaptic elements, but differs from the composition of the more general types of cell coat. This synaptic protein is less apparent in osmium-fixed material, possibly because osmium has a tendency to deaminate and break up proteins (Hake, 1965) as it fixes the tissue. The macromolecular protein matrix may be superimposed with carbohydrates, particularly within the synaptic cleft (Pappas and Purpura, 1966; Kelly, 1967; Bondareff, 1967) (Figure 7). Material that reacts with PTA can also be seen at other types of intercellular junctions, particularly those defined by Palade (Farquhar and Palade, 1963) as the junctional complexes, such as desmosomes or maculae adhaerens. This general type of junctional complex, seen also between certain elements of the nervous system (especially between dendrites or cell bodies, and between glia and vessels [Brightman and Reese, 1969]), differs from the specialized synaptic material in that the sides of the complexes are identical; that is, there are neither dense projections nor structural polarization of the general junctional material.

Does synaptic material assist in the process of synaptic transmission or only maintain adhesion between contacting elements? This material is difficult to find in the immature cortex, although the rate and time of its development can be correlated with the onsets of organized electrical activity and neuronal maturation (Figure 8; Aghajanian and Bloom, 1967c). The onset of neuronal reactivity within tissue cultures can also be temporally related to the formation of specialized interneuronal contacts (Bunge et al., 1965), a process that takes place without requiring electrical activity (Crain et al., 1968). These data suggest that the synaptic material may in some way be associated with the synaptic process, but do not specify what the participation is likely to involve.

It is the unique presynaptic configuration of the dense projections which distinguishes morphologically defined synapses from all other forms of junctional complexes. As to the functions of these projections, there appear to be two schools of thought: in one (Gray, 1966) the projections are

FIGURE 7 Drawing of idealized "synapse" showing the morphological features brought out by a variety of cytochemical techniques, including the specialized elements of the synaptic connection believed to be composed of pro-

teins, and the cell-coat materials, which may be interspersed with proteins of the synaptic cleft. (Drawn by Paul Andriesse for NRP.)

sites for vesicle attachment (? quantal release); in the other (Akert et al., 1969), they serve to guide vesicles to the uncluttered "synaptic" membrane between the dense projections.

Classification of mammalian synaptic types

Let us attempt to summarize the above data into a classification of the types of synapses seen and reported in a wide variety of fixations, regions, and species. This classification seems most easily broken into three major sets of criteria, based on the presynaptic, the postsynaptic, or the intersynaptic microstructure.

PRESYNAPTIC CLASSIFICATIONS The first major presynaptic classification would not require electron microscopy at all, but can be confirmed with Golgi or Glees staining of

FIGURE 8 The number of synaptic junctions per cubic millimeter in the molecular layer of rat parietal cortex at various ages during development. Each point is mathematically derived from crude counts of profiles of synaptic junctions within thin sections. The number of synaptic profiles in a sample of 10 electron micrographs was counted for a single animal at each age. An area of 90 square microns was covered in each micrograph. The density of synapticjunction "centers" was then estimated by first applying the Abercrombie correction, using the measured mean lengths of synaptic profiles. The mean lengths of synaptic profiles at each age were as follows: 12 days, 2466 Å; 13 days, 2359 Å; 14 days, 2242 Å; 16 days, 2152 Å; 18 days, 2242 Å; 20 days, 2271 Å; 35 days, 2310 Å; 63 days, 2516 Å; 84 days, 2289 Å. The thin sections (silver interference color) were assumed to be 700 Å thick. The corrected values for density were then doubled, because profiles were estimated to represent only about half of the total synaptic-junction centers within the sections. (From Aghajanian and Bloom, 1967c.)

neuroterminals, which distinguish them on the basis of their shape; that is, bouton versus club versus calyx-shaped endings of various sizes (see Bodian, 1967). A second criterion for presynaptic classification is whether the terminal is the actual termination of the axon or is one of a series of axonal enlargements that bear synaptic vesicle accumulations and make specialized contacts with dendrites or cell bodies: so-called en passant terminals. In this case, the word terminal really implies a functional point of secretion rather than a termination (Richardson, 1962, 1964); however, no experimental data exist on the assumed functional equivalence of seriatim "secretory" enlargements. The presynaptic element can also be classified structurally by vesicle shape, size, and electron opacity, or other cytochemical data on the transmitter. The appearance of the vesicle in the electron microscope may reflect, in part, the type of transmitter, the type of macromolecule binding the transmitter within the vesicle, and the protein synthetic properties of the membranes and axoplasm surrounding various types of vesicles (see above).

INTERSYNAPTIC COMPLEX Synapses may also be classified by the morphology of the specialized contact zone. Gray, on the basis of his material, classified synapses into two types, depending on the relative predominance of the specialized postsynaptic element stained with PTA (Gray, 1959, 1969; Palay, 1967). Those junctions that exhibited little or no postsynaptic specialization appeared to be more symmetrical than did others in which the postsynaptic specialization was its full 250 Å in thickness. The recent work of Colonnier (1968) has confirmed these gradations of synaptic specialization in osmium-stained material. On the basis of our E-PTA staining of glutaraldehyde-fixed material, examined without intervening osmium exposure, Aghajanian and I (Aghajanian and Bloom, 1967c) classified the morphology of synaptic junctions into three groups, which were distinguished primarily on the basis of the size and shape of the presynaptic dense projection. It was our belief that the variations were related to the relative maturation of the synaptic complex, although it may well be that the variations are actually caused by two distinct types of synaptic contacts, one with relatively little postsynaptic material and one with the full complement of such material.

POSTSYNAPTIC ELEMENTS Other specialized structures found within the postsynaptic elements also serve as a basis for discriminating types of synapses. These are not detailed here (see Milhaud and Pappas, 1966; and Robertson, this volume), but it may be well to point out that specialized forms of smooth endoplasmic reticulum and various configurations of postsynaptic electron-opaque material have been described without explanation.
Are synaptic variations significant?

These factual constraints, listed with, I hope, a minimum of interpretation, indicate the basic components of synaptic ultrastructure. Clearly, there is a high degree of variability, particularly in relation to the synaptic vesicles, to the synaptic specialization, and to the size, site, and shape of the contact. Let us then inquire whether these variations in synaptic form and composition are indications of differences in function. That is, do they point to: (1) inhibition or excitation; (2) the chemical transmitter secreted (such as ACh, NE, serotonin, dopamine, amino acid, or, possibly, some combination of these); (3) the location of the synapse, for example, axo-somatic, axo-dendritic (on either primary, secondary, or tertiary dendrites or on dendritic spines), axoaxonic on the hillock, or on a distal nerve terminal, or "dendrodendritic" contacts; or (4) a property of the two cells forming the contact. That is, do certain types of presynaptic cell tend to form particular types of junctions with special classes of postsynaptic cells? Clearly, that they do so would seem to be demonstrated for cerebellar cortex (Larramendi et al., 1967); cerebral cortex (Colonnier, 1968) and septum (Raisman, 1969a, 1969b). This concept indicates not only the possibility that growing nerve terminals have sought out certain cellular recognition phenomena in order to establish the proper kinds of contact, but, further, that the type of presynaptic innervation can modify the functional response of the postsynaptic cell (see Guth, 1969).

In terms of our original quest for information permitting us to do experiments at the structural level on possible changes involved in plasticity and learning, it would seem essential to eliminate variability and morphology caused by intrinsic geometry, transmitter type, location of synapse on cell (positioning), and the particular elements in the circuit. If these variables could be quantitated for particular defined junctions, it should be easier to design experiments in which changes in synaptic morphology could be related to the activity state of the joined neuronal elements. Without knowing such variables, certain investigators have attempted experiments of this nature in the retina (de Robertis and Franchi, 1956; Mountford, 1963), the superior cervical ganglion (Green, 1966), the neuromuscular junction (see Hubbard and Kwanbunbumpen, 1968), and the adrenal medulla (de Robertis and Vaz Ferreira, 1957). At best, the results indicate that there is some correlation between the distribution and number of synaptic vesicles and activity, but much further experimental confirmation is needed.

Proposals for synaptic plasticity

Kandel and Spencer (1968), in their review on cellular neurophysiological mechanisms of learning, pointed out

that there are two major schools of thought on the way in which interneuronal connections could be modulated by experience. One suggested basic mechanism is the formation of new connections between nerve cells; a second is modulation (that is, changes in efficiency of communication) across existing synaptic connections.

New CONNECTIONS If learning or memory requires the formation of new connections between neurons, the E-PTA staining method would seem to be ideal for experimental testing, because it simplifies the quantitation of synaptic contacts. With this in mind, we have performed several types of experiments attempting to quantitate the numbers of synaptic contacts in the molecular layer of the cerebral cortex of rats after a variety of behavioral and functional experiments (Aghajanian and Bloom, unpublished). We have compared the rate of formation of synaptic contacts in normal rats with those made hypothyroid by surgery. We have also tried to quantify synaptic contacts in the cortical molecular layer of animals subjected to "enrichment" (Krech et al., 1960). We have further compared the quantity of synaptic contacts in the visual cortex and motor cortex of rats raised in the dark with animals raised under normal lighting conditions, and have performed similar experiments on rabbits with one or both eyes sewn shut at birth, prior to the known perception of visual information (Foote, Aghajanian, and Bloom, unpublished). Such experiments are much easier to conceive and execute than to interpret. Thus far, the data have shown that little, if any, reproducible change takes place with these rather gross variations in functional loads. At best, hypothyroidism seems to delay, rather than to diminish, the total formation of synaptic contacts. The brain-enrichment procedures have had one intriguing result: although the enriched animals are different from the normal animals in numbers of contacts per unit volume of molecular-layer cortex, they are as likely to have more synapses as fewer.

The most reproducible changes we have observed have been in relation to visual deprivation, in which both the visual and the motor cortex of rats reared in the dark appear to have more synaptic contacts per unit area of molecularlayer cortex than do animals reared under normal lighting. One explanation could be that, because the rat is a nocturnal animal, being in the dark for extended periods of time caused its brain to be more active, hence forming more contacts. On the other hand, the increased number per unit area could simply be an artifact of variation in the size of nerve dendrites or terminals. Light-microscope analysis of Golgi-stained material (Globus and Scheibel, 1967; Valverde, 1967) shows that visual deprivation prevents the formation of dendritic spines in layer four of the visual cortex. Although this layer is different from that analyzed in our synapse-quantitating studies, it is possible that the

apical dendrites of these cells could also have been less well developed than under normal conditions. A concomitant decrease in the size of the dendrites would make the nerve endings appear to be closer together and, hence, result in a slightly higher content of synaptic contacts per unit area. This experiment has also been performed for electron microscopy with osmium-stained material rather than PTA-stained material (Cragg, 1967, 1969). Cragg interpreted his results on both visual cortex and lateral geniculate to indicate that there were fewer nerve contacts in animals deprived of visual information. His data are based on the assumption that every process that contains synaptic vesicles is a synapse. Unless these nerve endings are followed to specialized contacts, and unless one can verify the relative diameters of the nerve endings, the assumption may not be valid. Nevertheless, Cragg (1969) reported that, under the conditions of his experiments, geniculate terminals of lightdeprived rats are about 10 per cent wider, but 30 per cent less frequent. No corresponding dendrite measurements were made.

The most appropriate experiments for structural analysis of neural plasticity would include measurements of contact numbers and size, nerve terminals and their volume, and dendrites and their volume. These measurements would help significantly to eliminate apparent changes in number caused by changes in size of contacts or of contacting elements, which is the essence of the "new-versus-bettersynapses" choice. Still, the primary visual relay may not be the appropriate place to seek functional plasticity, for the physiological effects of disuse are small (Burke and Hayhow, 1968). Despite these possibly significant variations resulting from visual deprivation, we have been most impressed with the relative constancy of the E-PTA contacts from animal to animal of the same species. Without proving it, this constancy suggests that the genetic composition of the neuron may well have programed the number and types of connections it is to make. If so, it might be more profitable to propose experiments in which changes of plasticity would be analyzed in terms of the modulation of existing connections.

SYNAPTIC SPROUTING OR TRANSPOSITION We might also consider a compromise between forming new connections and modulating old ones. For instance, the genetic components of a neuron might program the basic number of axonal contacts with specific postsynaptic cells. With increases in activity, the original axon might sprout additional axon collaterals to the same postsynaptic cell. These secondary axon collaterals might even be permitted to be in contact with the cell closer to the axon hillock, where the influence of the presynaptic secretion on postsynaptic potentials would be relatively more important in terms of the discharge frequency or firing patterns of the postsynaptic cell. One might suppose that the same situation could arise if it were possible for nerve endings that originally come in contact with neurons on distal portions of the dendrite to migrate in their position of contact to regions closer to the cell body or axon hillock. The existence of sprouting can hardly be doubted; many lightmicroscope studies have attested to it (Liu and Chambers, 1958; Goodman and Horel, 1966). The methods for demonstrating it most effectively, however, have required that the area investigated first be partially de-afferented surgically, allowing weeks or months for the "sprouting" to take place from the residual nerves, which are then sectioned and again stained with silver techniques. This type of experiment has recently been analyzed fine-structurally (Raisman, 1969b) in the medial and lateral septal nuclei of the rat. The results here strongly support the existence of nerveterminal plasticity, in that certain systems of axons appear able to reinnervate synaptic sites vacated by degenerated lesioned axons of a separate system. As Raisman pointed out, if this potentiality of certain systems for terminal plasticity in any way reflects the changes associated with learning, it suggests that our concepts of the relative importance of specific connections may require re-evaluation.

BETTER SYNAPSES With such a possible exception, then, I propose that changes in synaptic plasticity be examined in terms of changes that could account for increased or decreased efficiency of transmission across existing terminals. We might think, offhand, of several cellular mechanisms by which synaptic efficiency could be affected. We have already alluded to the possibility that synaptic activity could modulate the size of the presynaptic nerve terminal (Bazanova et al., 1966) or the postsynaptic dendrite and, as a consequence, modify the size or amount of specialized synaptic material. One could then examine nerve endings for the ratio between the size of the apposed nerve membranes and the amount of E-PTA or BI staining material. Changes in the glial configurations could, depending on what cellular functions are eventually attributed to the glia, change the diffusion rate of the transmitter or its catabolism at the site, and contribute to transmission efficiency.

There are at least three other possible modulating circumstances we could consider, although their proof depends not only on fine-structure but, perhaps more importantly, on combined pharmacological and electrophysiological experimentation. One circumstance would be that activity within a given nerve circuit could alter the quantal efficiency by which transmitter is released for a given depolarization of the nerve terminal. It is not known, for example, whether "quanta" (see Katz, 1966; also Iversen, this volume) are equal among nerve terminals of different presynaptic cells or in their effects on different postsynaptic cells.

Although the physical explanation of the quantal effect is almost universally linked conceptually to the presence of synaptic vesicles (see Katz, 1966), this relationship is unproved, and the quantal nature of spontaneous transmitter release could depend on any quantalized aspect of excitation-secretion coupling (see Douglas, 1968). Furthermore, when the nerve terminal is depolarized, the amount of transmitter released to act on the postsynaptic cell is roughly proportional to the resting transmembrane potential at that time (Bloedel et al., 1966). The biological properties that account for the transfer constant relating change in nerve-terminal membrane potential to amount of transmitter released could be a testable opportunity for plasticity in synaptic efficiency. The modulation of this constant of all-or-none spike activity might be approachable from a structural point of view, if the relationship of the dense projections to the excitation-secretion coupling process could be clarified. In an earlier proposal, Gray (1966) suggested that synaptic vesicles tend to cluster around the dense projections, and that the dense projections might be a form of attachment of the synaptic vesicles. If such were the case, one might expect that the proteinaceous matrix of the dense projection could have some enzymatic function that causes the release of transmitter or facilitates access to the covert receptor site. In neuromuscular junctions incubated in vitro to induce increases in quantal release, increased numbers of presumed dense projections (actually seen as presynaptic membrane thickenings) were reported (Hubbard and Kwanbunbumpen, 1968).

Synaptic efficiency could also be modulated if the receptiveness of the postsynaptic element could be altered by changes in activity of the presynaptic element. In experiments on the postsynaptic receptivity of regenerating and reinnervating neuromuscular junctions (see Guth, 1969), the presence of the presynaptic terminal appears to decrease the receptive area of the postsynaptic element. Recently, we found that, in the immature cerebellar cortex of the rat (Woodward, Hoffer, Siggins, and Bloom, in preparation), the Purkinje cells are responsive to several of the potential transmitters before any synaptic contacts have appeared. Such data could indicate that the postsynaptic cells begin by being overly receptive and subsequently localize their responsiveness with nerve activity, as occurs with neuromuscular junctions. The factors responsible for such changes in size and quality of receptivity would also be suitable for plasticity.

A third, and equally unsubstantiated, proposal for synaptic modulation is that the transmitter substance may be able to do more than simply generate typical rapid postsynaptic ionic potentials. In addition to the more commonly accepted type of postsynaptic potentials that last 10 to 100 milliseconds (see Eccles, 1964), long-lasting postsynaptic potentials of seconds have been described recently from many portions of the autonomic nervous system of frogs and certain mammals (Tosaka et al., 1968; Koketsu et al., 1968), as well as in the molluscan nervous system (Pinsker and Kandel, 1969; Kerkut et al., 1969). These long-lasting postsynaptic potentials appear in some ways to be metabolic, in that they can be influenced by metabolic poisons and by temperature, but not by ions. Most importantly, they do not exhibit concurrent conductance changes to ions (Kobayashi and Libet, 1968). One such prolonged postsynaptic potential may be the result of the influence of the transmitter substance (in this case, dopamine) in stimulating an electrogenic pump, which results in a prolonged hyperpolarizing postsynaptic potential (Kerkut et al., 1969). From our studies on the cerebellar cortex (Siggins et al., 1969), we have proposed that one explanation for norepinephrine-induced depression of cerebellar Purkinje-cell activity could be by way of intermediation with cyclic adenosine monophosphate (C-AMP). The C-AMP reproduces the changes in spontaneous firing patterns seen with NE, although the onset and offset of the response are much faster with C-AMP. Furthermore, the response to NE can be blocked by prostaglandins, which are known to block the ability of NE to stimulate adenyl cyclase, the enzyme that synthesizes C-AMP. Additionally, the response to NE is potentiated by such inhibitors of phosphodiesterase as theophylline and aminophylline. By putting these bits of information together, we could postulate that the transmitter substance could somehow generate a prolonged postsynaptic potential in addition to the immediate postsynaptic ionic potential; the prolonged potential shift could arise by stimulating a metabolic electrogenic pump to hyperpolarize or depolarize the membrane over long periods of time. Such prolonged shifts in membrane potential could "modulate" the postsynaptic element and make it more-or-less receptive to its incoming signals. This proposal could account for the concept of neuromodulation, often postulated without precise, testable cellular mechanisms.

The synapse gap: its causes and cures

The prolonged descriptive history of electron microscopy sometimes frustrates the reader anxious to get on with experimental, fine-structural neurosciences. The preceding proposals require us to clarify certain of the descriptive variables among nerve terminals before we can hope to analyze for those changes that might take place with synaptic activity. If we were to propose the most ideal circumstances, we would require a system in which we could identify, with the electron microscope, the distinct type of nerve ending on a special type of postsynaptic cell (see Hendrickson, 1969, for a new method) the output of which is behaviorally important. We would hope to identify the transmitter or transmitters by which cell A can influence the activity of cell B, and to show that the connectivity of cell A to cell B could be modified by use. We would need to verify the existence of the transmitter by some cytochemical technique within these nerve terminals, as well as to satisfy the neurophysiological and neuropharmacological criteria of transmitter identification that are described in detail elsewhere (for reviews, see Bloom and Giarman, 1968a, 1968b).

But would such data establish the feasibility of ultrastructural analysis of neural plasticity? From our combinations of electrophysiology and fine structure, we believe that the responsiveness to NE and C-AMP that has been observed in Purkinje cells in the cerebellar cortex of the rat suggests a noradrenergic synapse. By using electron-microscopic techniques we can identify these nerve terminals studied by the electrophysiological approach. Yet, would these data on the potential noradrenergic innervation to the cerebellar cortex satisfy the criteria we have proposed here for a model pathway in which to examine the effects of synaptic plasticity? The answer to this question must be no, because, even though we can identify the site of the nerve ending on the postsynaptic cell and the cell bodies most likely to give rise to the synapse, the fact still remains that we do not know that Purkinje cells can "learn" anything in response to activity through the norepinephrine synapse. According to some (Young, 1966), the large cells, which are the ones most commonly recorded by electrophysiological methods, are the least likely to indicate modulating changes with experience or memory.

We may find, therefore, at the end of an infinitely difficult period of describing, organizing, and classifying nerve-ending patterns and particular synaptic connections, that those cells on which experiential modulation of synaptic activity takes place are the cells that are most difficult, if not impossible, to record with conventional electrophysiological methods. Thus, the main cause of the "synapse gap" in a molecular explanation of neural plasticity is that we do not yet know where to look nor what to look for. I hope that the factors pointed out here will at least serve to stimulate clarification. I believe the synaptic E-PTA material is protein; its implications are protean. Whether it will fill the "synapse gap" remains to be shown.

Conclusions

At the cellular level of inquiry, the synaptic connections of neurons present a specifiable restrictive site at which to analyze possible plastic changes induced by activity in a particular nerve circuit. Fine-structural descriptions provide a number of morphological indexes against which the activity-linked changes might be measured, such as the size and shape of the terminals, their relative position on the postsynaptic cell, the number, shape, and size of the preterminal vesicles, and the relative size and morphology of the synaptic specialization. To this purely morphologic base we can add both the histochemical dimensions, by attempting to identify the transmitter stored in the vesicles, and the physiologic dimensions, by observing the response of the postsynaptic cell to this transmitter administered by microelectrophoresis. Furthermore, we can approach the molecular level of inquiry by isolating the macromolecular proteins constituting the synaptic specialization; in the dynamic concept of the synapse, these macromolecules may influence the efficiency of transjunctional events. To close the synapse gap in our understanding of the link between behavioral and cellular events, however, the primary requirement is a bona fide synaptic connection in the brain at which physiologically induced activity can reveal verified plasticity in function.

DO Brain Glycomacromolecules and Interneuronal Recognition

SAMUEL H. BARONDES

THIS PAPER is concerned with one major hypothesis: that polysaccharides on neuronal surfaces play a crucial role in defining and regulating interneuronal synaptic relationships. This hypothesis has not wanted for supporters. For several decades, students of embryogenesis (e.g., Holtfreter, 1939; Weiss, 1941; Moscona, 1963, 1968; Steinberg, 1963; Grobstein, 1967; Heinmets, 1968) have suggested that intercellular recognition is determined by substances on the surface of cells. Because glycoproteins and glycolipids (referred to here collectively as either glycomacromolecules or heterosaccharides) are characteristic constituents of cell surfaces, they have frequently been proposed as candidates for this function (Gesner and Ginsburg, 1964; Dische, 1966; Kalckar, 1965; Brunngraber, 1969). Bogoch (1965, 1968) has emphasized their possible importance in the brain.

At present, the evidence in support of this hypothesis is, at best, indirect. It is being considered largely to stimulate investigation of the mechanism of interneuronal recognition. This problem, although generally identified as one of the most critical in neurobiology, has not received the experimental attention it deserves because of the anticipated technical difficulties. The purpose of this paper is to emphasize that glycomacromolecules may provide the key to the solution of this problem and that relevant biochemical experiments are possible.

The fact that polysaccharides, like those that determine blood-group specification, may be linked covalently either to lipid or protein (Watkins, 1967), underscores the importance of considering both these classes of glycomacromolecules in a discussion of cell surfaces. Because glycolipids of the nervous system are already being studied extensively for other reasons, I emphasize the glycoproteins, but to do so in no way disregards the possible role of glycolipids. Indeed, gangliosides, which are concentrated in neurons (Lowden and Wolfe, 1964)-particularly at nerve endings (Wiegandt, 1967)-merit special consideration in a discussion of the neuronal surface. Yet glycoproteins may prove to be of even greater significance in determining the properties of synaptic surfaces, because they appear to possess greater structural variability and because of the enormous volume occupied by their long, extensively hydrated polysaccharide chains (Schubert, 1964). When the properties of a membrane surface (e.g., Figure 1) are considered, the polysaccharide side chains of glycoproteins deserve particular notice not only because they may stick out fairly far but also because they may occupy enormous volumes caused by hydration. Adjacent cells would be expected to interact at this most superficial level.

Before I discuss what is known about glycoproteins in the nervous system, it is necessary to review general studies of their structure, metabolism, cellular localization and function. For more detailed summaries, the reader is directed to recent volumes edited by Rossi and Stoll (1968), Davis and Warren (1967), and Manson (1968); to recent reviews by Ginsburg and Neufeld (1969) and Cook (1968); and to a Neurosciences Research Program Bulletin on *Brain Cell Microenvironment* (Schmitt and Samson, 1969).

FIGURE 1 Hypothetical neuronal surface. Protruding carbohydrate residues from glycolipids and glycoproteins are shown, as envisioned by Lehninger (1968). Because of their greater length, the polysaccharide chains of glycoproteins may protrude farthest and may constitute the outermost portion of the cell surface.

General studies of glycoproteins

STRUCTURE OF GLYCOPROTEINS Confusing terminologies of the past have been superseded by the definition of glycoproteins as all molecules that contain carbohydrate residues covalently linked to protein (Jeanloz, 1968). A special class of these substances, the acidic mucopolysaccharides, consists of a long chain of two repeating sugars covalently linked to protein. The other glycoproteins have less regular structures. Because the component sugars exist in anomeric forms and have multiple potential sites for linear and branched linkages, the potentialities for structurally unique glycoproteins are enormous (Table I), although the polysaccharides of mammalian glycoproteins are generally constructed from only six sugars, some of which are found in characteristic positions (Table I).

The characterized glycoproteins differ markedly in structure (Table II). Some contain a large number of separate disaccharides per molecule of protein (ovine submaxillary glycoprotein), a single longer chain of carbohydrates per molecule of protein (hen ovalbumin), several identical, fairly long chains of carbohydrates per molecule of protein (fetuin), or a number of chains of two types per molecule of protein (thyroglobulin). The similar carbohydrate units may not be precisely identical either within the same molecule or within different molecules from the same tissue. This slight heterogeneity may be due to variability during synthesis or to variable degrees of degradation either in vivo or as an artifact of the isolation procedure. The function of this heterogeneity is not known.

METABOLISM Knowledge about the site of synthesis, mechanism of synthesis, and site of degradation of glyco-

proteins is only now being accumulated. It is believed that carbohydrates are not added to glycoproteins until after the completion of the entire polypeptide chain. Although some polypeptides released from polysomes by puromycin have been found to contain glucosamine residues (Lawford and Schacter, 1966; Molnar and Sy, 1967), there is general agreement that carbohydrate incorporation is not dictated by ribonucleic acid templates. Rather, the addition of sugars is determined by the structure of the protein and the presence of appropriate glycosyl transferases in the cell. These enzymes are believed to be concentrated in the smooth endoplasmic reticulum (Hagopian et al., 1968).

The generally accepted position is that, on release of polypeptides from polysomes, appropriate sugars are sequentially incorporated from nucleotide sugars by specific glycosyl transferases. The sugars are presumably added one at a time, so that incomplete glycoproteins become substrates for the next enzyme in the sequence. Uridine diphosphate (UDP)trisaccharides have, however, been found (Jourdian and Roseman, 1963) that could be intermediates in transfer of the trisaccharides to appropriate acceptors.

Polypeptide chains that will become glycoproteins are probably recognized by glycosyl transferases in a highly specific manner. The enzyme that transfers N-acetylgalactosamine to the hydroxyamino acid residues of ovine submaxillary glycoprotein will not transfer this sugar to a large number of other potential acceptors (McGuire and Roseman, 1967). Specificity is also shown in genetic studies correlating specific blood group substances with the presence or absence of specific glycosyl transferases. These studies indicate that addition of the same sugar to different incomplete polysaccharide chains may be dictated by different transferases. Thus, there are specific fucosyl transferases (Shen et al., 1968) responsible for the addition of each of the two fucose residues that determine the Lewis blood group:

Fuc-a-
$$(1\rightarrow 2)$$
-Gal- β - $(1\rightarrow 3)$ -GluNac-R
Fuc-a- $(1\rightarrow 4)$

Regulation of glycoprotein synthesis may involve other factors, in addition to the availability of appropriate acceptors, transferases, and nucleotide sugars. In bacterial systems, there is evidence for the transfer of sugars from nucleotides to lipid intermediates prior to their incorporation in polysaccharide chains (Weiner et al., 1965). An "acceptor complex" that contains lipids in addition to the sugar acceptors has been described by Rothfield and Horecker (1964). The entire complex interacts in some manner with the transferase. The existence of such complexes may be of considerable importance in preventing incorporation of erroneous sugars. In systems treated in vitro with detergents, "artificial glycoproteins" may be produced by the incorporation of sugars they do not contain normally (Bosmann et al., 1968).

TABLE I

Potentialities for and Constraints on Structural Complexity of Glycoproteins

- I. Potentialities for Structural Complexity
 - 1. Sequence of sugars
 - 2. Anomeric form of sugar (α or β)
 - 3. Position of attachment to neighboring sugar (e.g., $1 \rightarrow 3$; $1 \rightarrow 4$)
 - 4. Branching
 - 5. Length of polysaccharide units
 - 6. Position on polypeptide to which polysaccharide attached
 - 7. Number of polysaccharides per polypeptide
 - 8. Substitution of other groups (e.g., sulfate)

II. Some Constraints on Structural Complexity

- 1. Limited number of sugars:
 - N-acetylglucosamine, N-acetylgalactosamine, galactose, mannose, fucose, sialic acids (also: glucose, xylose, glucuronic acid)
- 2. All in D-configuration, except L-fucose
- 3. All in pyranose ring form
- 4. Innermost linkages:
 - N-acetylglucosamine-amide N of asparagine (commonest) N-acetylgalactosamine-OH of serine or threonine also: galactose-OH of hydroxylysine (collagen)
 - xylose-OH of serine (mucopolysaccharides)
- 5. Fucose and sialic acids always terminal

(Based on reviews by Roseman, 1968, and Ginsburg and Neufeld, 1969.)

		Residu	1es per Carbohydra	te Unit		Mol. Wt. of Carbohyd.	No. of Units per Molecule
Glycoprotein	galactose	mannose	hexosamine	sialic acid	fucose	Unit	Protein
Ovalbumin (hen)		5	3			1420	1
Submaxillary glycoprot							
(ovine)			1	1		494	800
Fetuin	4	3	6	4		3520	3
Thyroglobulin (calf)							
Unit A		10	2			2030	4-5
Unit B	4	3	5	2	1	2880	14

 TABLE II

 Carbohydrate Units of Glycoproteins

(Adapted from Spiro, 1968.)

A general principle of glycoprotein metabolism, which has been emphasized by Eylar (1966), is that addition of carbohydrates to proteins is a prelude to *secretion*. The completed glycoprotein is secreted either onto the cell surface or into the extracellular space (including the blood stream). Recent studies (Swenson and Kern, 1968) have shown that the addition of sialic acid to gamma globulin immediately precedes its secretion from plasma cells. The addition of glycomacromolecules to the cell surface apparently occurs in an orderly manner by spread from one region of the

membrane rather than by random appearance at multiple sites over the cell surface, as was shown in studies of the pattern of reappearance of sialic acid residues removed from cultured cells by neuraminidase (Marcus and Schwartz, 1968).

Little is known about the mechanism of degradation of the glycoproteins. Although they are typically extracellular, the enzymes which apparently degrade them are present in lysosomes within the cell (Aronson and de Duve, 1968). That these enzymes normally function in their degradation has been shown by the lysosomal accumulation of glycopeptides and glycolipids in patients with a genetically determined deficiency in one of these degradative enzymes. Degradation is believed to occur in lysosomes, so there may be a mechanism for entry into cells of surface glycoproteins and circulating glycoproteins.

LOCALIZATION ON CELL SURFACES Evidence for the localization of glycomacromolecules on cell surfaces has been derived from histological studies and from enzymatic degradation of the surface of living cell suspensions. The histochemical techniques are based on reactions believed to be specific for polysaccharides or on reactions based on the presence of negatively charged groups often inferred to be sialic acid residues. Because both glycoproteins and glycolipids are probably retained on the cell despite fixation and histological processing, these techniques do not distinguish between them. Many studies show the presence of thick or thin polysaccharide coats on a variety of cells. Much of this work has been reviewed by Revel and Ito (1967). Particularly noteworthy are electron-microscope studies by Rambourg and Leblond (1967) showing glycomacromolecules on cell surfaces that have been treated first with periodic acid and then with silver methenamine, and the studies of Pease (1966), who has used phosphotungstic acid as a stain for what he believes are polysaccharide chains.

In the enzymatic studies, suspension cultures of cells are washed, incubated with a proteolytic enzyme or with neuraminidase, and the released sugars and residual sugars in the living cells are analyzed. Wallach and Eylar (1961) found that similar amounts of sialic acid were released by neuraminidase treatment of intact or ruptured ascites carcinoma cells, suggesting that sialic acid-containing molecules are abundant on the cell surface. Shen and Ginsburg (1968) found extensive release of both sialic acid and a variety of other sugars, characteristically present in glycoproteins, when HeLa cells in suspension culture were treated with trypsin. The combination of the histochemical and enzymatic studies leaves little doubt that the surface of the cell is rich in bound carbohydrates and that a substantial portion of the total cellular content of these substances is localized on the surface.

ROLE IN INTERCELLULAR RECOGNITION That carbohydrate substances on cell surfaces have unique and recognizable structures has been well known since the demonstration that capsular polysaccharides of pneumococcus and blood-group substances on human erythrocytes may be recognized by specific antibodies. Whether there is such high specificity in recognition of one cell surface by another is unknown. Two types of experiments suggest that these substances play some role in intercellular recognition—isolation of substances that promote cellular interactions and studies of the effects of enzymatic removal of sugars from cell surfaces. The first method has been pursued most extensively in sponge (reviewed by Humphreys, 1967; Moscona, 1968). A glycoprotein-rich material, which is released from the surface of sponge cells in calcium-free media, has been shown to play a role in aggregating specific species of sponge cells. The material from one species aggregates only dissociated cells from the same species and not from a different species, which is taken as evidence of considerable specificity. Likewise, glycoproteins from yeast have been implicated as being responsible for sexual recognition (Crandall and Brock, 1968).

Other studies have been less direct and concern themselves primarily with the role of surface neuraminic acid on various recognition functions of cells. The binding of viruses to cells has been inhibited by pretreatment of the cells with neuraminidase (Gottschalk, 1960), and the action of serotonin on smooth-muscle cells has been interfered with by treatment of the cells with that enzyme (Woolley and Gommi, 1965). Treating lymphocytes with neuraminidase (Woodruff and Gesner, 1967) or with a mixture of glycosidases (Gesner and Ginsburg, 1964) has interfered with their accumulation in the spleen. Treating rabbit ova with the same enzyme has been shown to inhibit sperm penetration (Soupart and Clewe, 1965). These studies suggest, in general, that neuraminic acid on cell surfaces, which might be either in glycoproteins or glycolipids, confers some recognition function on these surfaces. On the basis of available evidence the recognition shown could be very crude. It remains to be shown that more highly specialized recognition functions are mediated by sugar-rich substances. Presently this is supported only by the teleological notions that the sugar-rich structures present on cell surfaces are suitable for coding functions (Bogoch, 1968), and that such functions apparently exist.

Glycoproteins in brain

AMOUNT, DISTRIBUTION, AND COMPOSITION Brunngraber (1969) has estimated that between 3 per cent and 10 per cent of all brain proteins are glycoproteins. This calculation is based on the finding that there is approximately 1 milligram of carbohydrate incorporated in 100 milligrams of brain protein, and that the percentage of carbohydrate in glycoproteins is generally between 10 per cent and 33 per cent. More than 50 per cent of total brain hexosamine and approximately 20 per cent of brain sialic acid are present in nondialyzable glycoprotein fragments obtained by papain digestion of brain protein after removal of glycolipids (Brunngraber, 1969).

The distribution of brain glycoproteins has been studied by histochemical techniques, with the use of light and electron microscopy. Periodic acid-Schiff staining material is concentrated in the neuropil (Hess, 1955, 1958), and several studies with the electron microscope (Pease, 1966; Bondareff, 1967; Rambourg and Leblond, 1967) show that it is localized on cell surfaces and particularly at synaptic junctions (Figure 2). Regenerating axon tips are rich in polysaccharides (Young and Abood, 1960). Nerve-ending fractions isolated by sucrose gradient centrifugation are richer than other brain fractions in both glycoproteins and gangliosides (Brunngraber et al., 1967). All these studies point to a special role for sugar-containing proteins and lipids at synapses.

Relatively little is known about the composition of brain glycoproteins. Mucopolysaccharides of the types found in many other tissues have been identified in brain (Margolis, 1967). A sialic acid containing glycoprotein was found in the a_2 -globulin fraction of soluble extracts of brain (Warecka and Bauer, 1967). Immunoelectrophoretic studies suggest that this glycoprotein is present only in brain. A glycoprotein with a molecular weight estimated at 30,000 has been identified in 90 per cent acetone extracts of brain and is also believed to be found uniquely in this tissue (Kuhn and Müldner, 1964; Gielen, 1966). The major glycoprotein detectable by periodic acid-Schiff staining in soluble extracts of five-day-old mouse brain studied by electrophoresis has an apparent molecular weight in the range of 250,000 (Dutton and Barondes, 1970), whereas particulate fractions from brain contain a wide range of glycoproteins.

"Sialomucopolysaccharides," obtained by papain digestion of defatted brain, have been studied extensively(Brunngraber, 1969). Although these substances can be fractionated in a variety of ways, Brunngraber believes that they all possess the same repeating unit, which consists of hexose and hexosamine, but differ in the relative number of attached sialic acid and fucose residues.

METABOLIC STUDIES Direct studies of glycosyl transferases in brain have been made primarily with sialyl transferases involved in ganglioside synthesis (Roseman, 1968). It is not clear whether similar or different sialyl transferases are involved in glycoprotein and glycolipid synthesis in brain. Den and Kaufman (1968) have reported that glycosyl transferases are abundant in nerve-ending particles prepared from embryonic chick brain. A fucosyl transferase has been found in brain microsomal fractions that transfers fucose from guanosine diphosphate (GDP)-fucose to a large number of incomplete endogenous glycoproteins in the preparation (Zatz and Barondes, unpublished). A mannosyl transferase, which transfers mannose from GDP-mannose to an unidentified glycolipid, has also been identified in brain (Zatz and Barondes, 1969). Caccam et al. (1969) have speculated that a similar enzyme might create a glycolipid intermediate, which is involved in glycoprotein synthesis. In vivo glycoprotein metabolism in mouse brain has been

examined somewhat more extensively. A unique aspect of brain glycoprotein metabolism appears to be the marked delay between synthesis of some polypeptide acceptors in the nerve-cell body and the addition of carbohydrates to these polypeptides only after they have been transported to nerve endings. This has been studied by observing the time course of incorporation of radioactive leucine (Barondes, 1964, 1968a) and glucosamine (Barondes, 1968b; Barondes and Dutton, 1969) into subcellular fractions of mouse brain at various times after intracerebral injection of these precursors. Radioactive leucine was incorporated rapidly into the protein of all subcellular fractions of brain, with the exception of the soluble component of the nerve-ending fraction (Table III). The soluble component of the nerveending fraction is obtained by lysing the fraction with water. This component has been a primary object of study because it is less contaminated by other brain constituents than is the particulate component of the nerve-ending fraction. The specific activity of the protein of the soluble component of nerve endings rose progressively for days after administration of the radioactive amino acid (Barondes, 1964, 1968a), presumably owing to transport of protein from the perikaryon to the nerve ending. In contrast, radioactive glucosamine was incorporated without delay into all subcellular fractions of brain, including the soluble protein of nerve endings (Table III), suggesting that some polypeptide chains formed in the nerve-cell body were modified by the addition of carbohydrates on arrival

This conclusion was confirmed by studies of the effect of acetoxycycloheximide, a potent inhibitor of cerebral pro-

at the nerve ending.

TABLE III

Incorporation of ³H-leucine and ¹⁴C-glucosamine into macromolecules of subcellular fractions of brain 3 hours and 6 days after injection. Mice were injected intracerebrally with a solution containing L-leucine-4, 5-³H and D-glucosamine-1-¹⁴C. Groups of mice were sacrificed either 3 hours or 6 days after injection; subcellular fractions were obtained, precipitated, washed and counted. (For details see Barondes, 1968b.)

FIGURE 2 Glycomacromolecules at cell surfaces and synapses. Rat cerebral cortex was prepared (A) by the periodic acid-silver methionine technique (Rambourg and Leblond, 1967) and (B) by the chromic acid-phosphotungstic acid technique (Rambourg et al., 1969), both of which stain glycomacromolecules. Neuronal and glial processes are separated from each other by stained material (vertical arrows), but staining of the intercellular space is markedly increased in the region of the synaptic cleft (horizontal arrows). Mitochondria (M) and multivesicular bodies (mv) are also stained. Magnification \times 20,000. The electron micrographs were kindly provided by Dr. A. Rambourg. tein synthesis, on incorporation of glucosamine into glycoproteins (Barondes and Dutton, 1969). Acetoxycycloheximide interferes with such incorporation by inhibiting the synthesis of protein acceptors for sugars. Within two hours after injection of acetoxycycloheximide, marked inhibition of glucosamine incorporation into brain glycoproteins was observed. There was, however, relatively little inhibition of incorporation into the soluble glycoproteins of the nerve-ending fraction (Table IV), suggesting that the polypeptide chains synthesized before the administration of acetoxycycloheximide continued to flow to the nerve ending, where carbohydrates may be added. Rahmann (1968) has recently shown, by autoradiographic studies with the light microscope, that tritiated glucose is incorporated into what appear to be macromolecules in the neuropil. Although the resolution that can be achieved is limited and the products Rahmann is studying have not been clearly identified, these results are consistent with those arrived at by subcellular fractionation.

Studies with the subcellular fractionation technique have also indicated that turnover of soluble glucosamine-labeled glycoproteins is relatively rapid at nerve endings. This has been demonstrated in studies in which acetoxycycloheximide was used to diminish the amount of labeled perikaryal glycoprotein arriving at the nerve ending (Figure 3) and in the absence of this inhibitor. Although fucose is incorporated relatively poorly into all soluble brain glycoproteins, there was a relatively rapid turnover of fucose-labeled

TABLE IV

Effect of acetoxycycloheximide on incorporation of radioactive glucosamine into brain glycoproteins. Mice were injected subcutaneously with 240 micrograms of acetoxycycloheximide or with saline 2 hours before intracerebral injection of ¹⁴C-glucosamine. They were killed 2 hours after glucosamine administration, and their cerebral hemispheres were fractionated and assayed. (For details see Barondes and Dutton, 1969.)

FIGURE 3 Relatively rapid turnover of some soluble glycoproteins of nerve endings (N.E.). Mice were injected with 14 C-glucosamine two hours after subcutaneous administration of acetoxycycloheximide. They were sacrificed at the indicated times after injection of glucosamine. (For details, see Barondes and Dutton, 1969).

soluble glycoproteins which were associated with the nerveending fraction (Zatz and Barondes, 1970).

Some aspects of neuronal glycoprotein metabolism suggested by these studies are shown in Figure 4. Some, possibly all, polypeptide chains that will become nerveending glycoproteins are made in the perikaryon. At this site, some may receive only a fraction of the sugars they will ultimately contain, or none at all. Incomplete glycoproteins are transported down the axon to the nerve ending. At the nerve ending, glycosyl transferases add further carbohydrates. The completed glycoproteins then "turn over" relatively rapidly, either because of degradation or, more likely, because of secretion from the nerve terminal. The secreted material may coat the nerve-terminal membrane or may migrate into the intersynaptic gap substance or some other site.

DEVELOPMENTAL STUDIES Studies of the accumulation of periodic acid-Schiff reacting material in the neuropil as mouse brains matured were reported by Hess (1955). He found that this material progressively accumulates between the fifth and fourteenth postnatal days. Warecka and Müller (1969) and Bogoch (1968) have reported maturational changes in human brain glycoproteins. Accumulation of gangliosides in rat brain occurs between five and 20 days after birth, and there is maximal synthesis at about days 10 to 12 (Kishimoto et al., 1965; Suzuki, 1967).

BRAIN GLYCOMACROMOLECULES AND INTERNEURONAL RECOGNITION 753

FIGURE 4 Transport of glycoprotein precursors and glycoproteins in usual mammalian cells and in neurons. In usual cells, sugars are believed to be added to glycoproteins in the smooth endoplasmic reticulum (E.R.) before they are se-

creted onto the cell surface or into the intercellular space. In neurons, polypeptides that were transported in axons may receive sugars at nerve terminals prior to secretion.

Because of the possible role of glycoprotein synthesis in synapse formation, we have begun studies on synthesis of glycoproteins in developing mouse brain (Dutton and Barondes, 1970). Studies of incorporation into both soluble and particulate glycoproteins have been made with the polyacrylamide gel techniques developed by Maizel (1966). Incorporation of either radioactive glucosamine or radioactive fucose into glycoproteins of developing brain was studied. Although the results with both sugars are very similar, we have preferred to use the latter, because fucose, in contrast with glucosamine, is not a known constituent of the mucopolysaccharide group of glycoproteins, and is neither converted to other sugars nor incorporated into glycolipids in brain (Zatz and Barondes, 1970).

The major finding of these studies is that, during brain development, there is extensive synthesis of glycoproteins, which migrate slowly in an electrophoretic system in which migration is correlated with molecular weight (Shapiro et al., 1967). Synthesis of these substances diminishes markedly between 10 and 15 days after birth, and is at a very low level thereafter. When one-day-old mice were injected intracerebrally with radioactive fucose, and the soluble brain glycoproteins, obtained 24 hours later, were electrophoresed, one major, slowly migrating peak (peak I) of radioactive glycoprotein was found (Figure 5). The soluble proteins obtained when fucose injections were made in fiveday-old mice showed two prominent slowly migrating peaks (I and II, Figure 5) and a smaller third peak, which migrated slightly farther. Synthesis of the glycoproteins in peak I is prominent in one-day-old mice, whereas peak II becomes prominent about three days after birth. The glycoproteins in peaks I and II are extensively synthesized until about 11 days after birth, but their synthesis has diminished markedly at 15 days after birth, and is not prominent in the adult (Figure 5).

Particulate brain glycoproteins synthesized by mice injected with labeled fucose at five days of age are distributed over a wide range (Figure 6). In contrast with adult brains particulate glycoproteins that, relatively, migrate more slowly, are synthesized in five-day-old brains (Figure 6). Upon calculation of the ratio of five-day-old to adult radioactive glycoprotein at each point on the gel, in order to factor out the adult particulate glycoproteins that are being synthesized in the five-day-old brain, the presence of peaks I and II becomes apparent in the particulate preparations of the five-day-old group (Figure 7). This was true when the mice were sacrified either three or 24 hours after the injection of radioactive fucose (Figure 7). In contrast with brain, the patterns of glycoproteins synthesized in fiveday-old and adult kidney do not show this difference (Figure 7).

The major glycoprotein detected by staining gels with the periodic acid-Schiff procedure, after electrophoresing the soluble fraction from five-day-old mice, corresponds

FIGURE 5 Polyacrylamide gel electrophoresis of soluble brain proteins. Adult, 5-day-old and 1-day-old mice were injected intercerebrally with ³H-leucine and ¹⁴C-fucose. They were sacrificed one day later, and soluble proteins were obtained by centrifugation of homogenates for one hour at 100,000 × gravity. The labeled proteins were treated with sodium dodecyl sulfate (SDS) and urea, reduced, alkylated, applied to polyacrylamide gel columns at 0, and electrophoresed in 0.1 per cent SDS by the method of Maizel (1966). The migration of proteins in this system is a function of molecular weight (Shapiro et al., 1967), but glycoproteins might behave anomalously. The migration of two standards, gamma globulin and albumin, is shown. The large peak of leucine-labeled protein has been shown to be microtubular protein (Dutton and Barondes, 1969). For details, see Dutton and Barondes, 1970.

FIGURE 6 Polyacrylamide gel electrophoresis of particulate brain proteins. The particulate proteins were obtained, treated as in Figure 5, and electrophoresed. The sample from the 5-day-old mice contained a wide range of high-molecular-weight, fucose-labeled proteins. (From Dutton and Barondes, 1970.)

with peak I. Studies of turnover after injection of radioactive fucose in five-day-old mice indicate that the fucoselabeled glycoproteins of peak II have a half-life in the range of one week, which is similar to that of total fucose-labeled soluble brain glycoproteins. In contrast, the turnover of the fucose-labeled glycoproteins in peak I is very much slower (Dutton and Barondes, 1970).

We are presently attempting to analyze chemically the glycoproteins in peaks I and II and to localize them by radioautography. Preliminary studies demonstrate marked incorporation of radioactivity in the neuropil of five-dayold mice. In view of the developmental studies of Hess (1955), it is possible that these substances are related to the PAS-stained material in neuropil. The striking differences in the metabolism of the glycoproteins of peaks I and II suggest that they may play different roles in brain development.

A model for interneuronal recognition

In this section, I attempt to demonstrate the plausibility of the notion that interneuronal recognition could be mediated

FIGURE 7 Ratios of particulate fractions from brain and kidney of 5-day-old-mice to those of adults. Adult and 5-day-old mice were injected with ¹⁴C-fucose and sacrificed 3 or 24 hours later, as indicated. Particulate proteins from brain and kidney were electrophoresed as described in Figure 5. By plotting the indicated ratio, the presence of peak I and peak II in particulate fractions of 5-dayold brain is apparent. This is not seen in the samples from kidney.

by surface glycomacromolecules by proposing, for the sake of argument, means whereby this could be brought about.

The best description of the specificity of interneuronal connections and the laws it apparently follows is in the retinotectal system, the development of which is considered in this volume by Marcus Jacobson. In essence, the work of Sperry (1963), Jacobson and Gaze (1965), De Long and Coulombre (1965), and Jacobson (1968) has demonstrated that the connections between regions of the retina and the tectum are rigidly specified at a precise time in development, long before the axons of retinal neurons have grown out to meet and make synapses with tectal neurons. Beyond this point in development, specification is so fixed that, when the eye is rotated, retinal cells still synapse with those tectal cells they would have sought out had the eye remained in its normal position. Jacobson (1968) has presented evidence that specification occurs first in one direction and then perpendicularly.

From these studies it seems likely that both the retina and the tectum are independently specified. Models based only on retinal cells' maintaining positions relative to one another, without specification of tectal cells, could also explain the findings in the normal animal. The evidence for the re-establishment of normal connections, however, after optic-nerve section and *ablation* of a portion of the retinal or tectal cells (Attardi and Sperry, 1963; Jacobson and Gaze, 1965), is more suggestive of mutual recognition by the cells that connect.

If specific groups of retinal cells do indeed recognize specific groups of tectal cells, this could be based on "identity" reactions (like recognizes like), as suggested by Roberts and Flexner (1966), or on "complementary" reactions (opposites attract). The experiments show what may be considered a "complementarity" of connections, in that dorsal cells in the left retina make contact with ventral cells in the right tectum and anterior cells in the left retina make synapses with posterior cells in the right tectum (Figure 8). As will be shown, this is consistent with recognition based on complementary cell surfaces.

For the purpose of this discussion, let us consider that both retinal cells and tectal cells are specified by "gradients of inducers." In this view, one inducer, localized in the midline, spreads laterally and progressively induces changes in responsive tissues. The anterior (nasal) retinal and tectal cells, which are closer to the midline, would be exposed to a higher concentration of this inducer than would the posterior (temporal cells). A second inducer might spread dorsoventrally, thereby inducing changes primarily in the dorsal tectal or retinal cells. Were this view correct, retinal cells could be considered as making synapses with tectal cells which had received complementary quantities of inducer-that is, the most dorsal and anterior retinal cells would have been strongly influenced by both the midline and the dorsoventral gradients and would make contact with those most posterior and ventral tectal cells that had been least exposed to these inducers.

The nature of the cellular changes produced by the putative inducers is not clear. Presumably a *permanent* alteration in gene expression is produced by some mechanism common to all differentiative processes. For the purpose of this discussion, it is assumed that this change leads ultimately to a systematic alteration in the surface heterosaccharides of retinal and tectal cells. If such an assumption be accepted, a scheme will be proposed to illustrate how surface heterosaccharides could mediate the observed phenomena. Let us assume the following: (1) there is a large number of protein and lipid molecules on the membranes of all neurons to which polysaccharide chains may be linked covalently; (2) the addition of sugars to these surface

FIGURE 8 Schematic plan of retinal-tectal connections. Axons from retinal ganglion cells grow out and synapse with tectal cells in the regions indicated by the same number. Symbols used are: A, anterior or nasal; D, dorsal; P, posterior or temporal; V, ventral. The positions shown are those during the period of specification and were confirmed in discussions with C. Coulombre and M. Jacobson.

proteins and lipids is linearly related to the level of the various glycosyl transferases in the cell over a wide range; (3) the polysaccharide chains that are formed have a far greater binding affinity for membrane proteins than for other polysaccharide chains.

Given these assumptions, let us now postulate that the putative inducer in one direction induces the synthesis of several glycosyl transferases, perhaps a hexosyl transferase and a hexosaminyl transferase, the presence of which in the cells will lead to the synthesis of long-repeating polysaccharide chains. Let us also postulate that an inducer in a perpendicular direction leads to the synthesis of graded amounts of a sialyl transferase. This enzyme may transfer charged sialic-acid residues to polysaccharide chains, which are present in relatively large quantities on the surface of all the cells in question, so that the quantity of the sialyl transferase is strictly limiting over a wide range. Because graded quantities of these enzymes are present in the cells

FIGURE 9 Hypothetical specification of retinal ganglion cells and tectal cells by the same gradients of inducers. The putative inducer, which spreads from the midline in a nasotemporal direction, influences primarily the nasal retinal and tectal cells, which, in most terminologies, are referred to as "anterior." The putative inducer that spreads in a dorsal-ventral direction influences primarily the dorsal retinal and tectal cells. Connections are ultimately made between cells that have complementary surfaces. Symbols used are the same as in Figure 8.

in question, the pattern of carbohydrates on the entire surface of neurons in both the retina and the tectum could be schematized as shown in Figure 9. Cells close to the inducer of hexosyl and hexosaminyl transferases have surfaces with many long polysaccharide chains composed of repeating units and are designated as completely black in the Figure. Those most distant from the focus have chains that are relatively fewer and shorter; these are shown as mostly white. The negatively charged sialic acid residues added to these polysaccharide chains would be distributed as indicated in the Figure.

Retinal cells abundant in polysaccharides would tend to make contact with tectal cells, which are poor in polysaccharides, because the latter would have many free surface proteins, which are not already binding polysaccharides. Interneuronal interaction would also be regulated by surface charge, with strongly negative surfaces repelling one another. The net result would be that the black negative cells would tend to come in contact with the primarily white and uncharged tectal cells as shown in the Figure. Through this comparatively simple scheme the observed retinotectal relationships could be established.

I must emphasize that there is no evidence at present for such a scheme. It is based on a large number of assumptions, any of which could be incorrect. It deliberately avoids assumptions about specific interactions between polysaccharides (other than mutual repulsion of negative charges), because interactions between these compounds is poorly understood at present. Rather, it emphasizes an attraction between polysaccharides on the one hand and proteins on the other. Although these could be highly specific, as shown by the existence of highly specific antibodies (proteins) for given polysaccharide chains, much less specific interaction could be operative (Steinberg, 1963).

The assumptions about gradients of inducers and about complementarity of the retina and tectum are consistent with present information but are not necessary to explain what is already known. Therefore, the primary value of this model is that it illustrates how, without very detailed information, protuberant glycomacromolecules on neuronal surfaces might dictate interneuronal recognition in the absence of rigid templates for highly deterministic structural specificity. Although the model is consistent with known facts, it does not deal with everything that is known. In particular, no attempt is made to explain how the effect of the "gradients of inducers," presumed to be present only in embryogenesis, is maintained through the life of the organism.

Summary

This paper considers the hypothesis that glycomacromolecules (glycolipids and glycoproteins) on neuronal surfaces mediate specific interneuronal recognition. The structure, metabolism, and localization of glycoproteins in cells are briefly reviewed. The capacity of nerve terminals to add carbohydrate residues to polypeptides synthesized in the neuronal perikaryon is shown, and the synthesis of several high-molecular-weight glycoproteins during a specific period in the development of the nervous system is described. A model for interneuronal recognition based on complementarity of cell surfaces in the retinotectal system is proposed, primarily to provoke biochemical investigation of this crucial problem.

The Investigation of Synaptic Function by Means of Subcellular Fractionation Techniques

V. P. WHITTAKER

TRADITIONAL BIOCHEMICAL techniques have given much information about the chemical composition of the brain; indeed, many of the ubiquitous constituents of animal cells (e.g., the phospholipids) were first isolated from brain tissue.

However, such information is not sufficient for an understanding of how the molecular constituents of nervous tissue are organized at the cellular level. Histochemical and autoradiographic techniques can make valuable contributions in particular instances, but a more general approach is provided by the technique of subcellular fractionation, in which cell structure is broken down by the controlled application of liquid shear forces. The cell fragments and organelles so produced are identified and characterized by a combination of morphological and chemical analysis.

Brain tissue, with its multiplicity of cell types, would be an unpromising subject for this kind of examination, if it were not for an unexpected property of presynaptic nerve terminals: their resistance to breakdown by liquid shear forces is much greater than is that of glial cells and other portions of neurons (Figure 1). This resistance permits the isolation of presynaptic nerve terminals (Gray and Whittaker, 1962) as sealed structures, to which we have given the name synaptosomes (Whittaker et al., 1964). Other structures that can be isolated by subcellular fractionation include fragments of myelinated axons, glial fragments, nuclei, mitochondria, and lengths of preterminal axon.

Synaptosomes may be used for a variety of purposes, of which the most important are as follows. Most obviously, they can be used for studying the mechanisms of synthesis, storage, release, and ultimate destruction of transmitter substances, and the effects of drugs and toxins on these processes.

By subfractionating synaptosomes, one can study the molecular organization of the presynaptic terminal—the composition of the external membranes, synaptic vesicles, soluble cytoplasm, and intraterminal mitochondria (Eichberg et al., 1964; Whittaker, 1966b). A certain proportion of synaptosomes have postsynaptic adhesions (Figure 1); as a result, they can, in principle, be used as a source of cleft material, of postsynaptic membranes, and of postsynaptic receptors, although caution is needed (Marchbanks and Whittaker, 1969; Whittaker, 1969a) in evaluating work done so far (Azcurra and De Robertis, 1967) on these lines.

Synaptosomes are formed, as far as we know, from any type of ending; the mossy-fiber endings in the glomerular layer of the cerebellar cortex pinch off to form synaptosomes that are sedimented at an unusually low speed, on account of their large size (Israël and Whittaker, 1965). Synaptosome preparations are, accordingly, source material for the identification of new transmitter substances, and extracts can be tested on neurons from regions of the brain from which the synaptosomes have been isolated (Krnjević and Whittaker, 1965).

Synaptosomes can be used to provide samples of terminal axoplasm in studies of axoplasmic flow (Barondes, 1966).

The degree of metabolic autonomy of the terminal region of the neuron may be gauged by comparing the incorporation of radioactive precursors into synaptosomes in vitro with that of nerve terminals isolated from more organized preparations (e.g., slices) after exposure of the latter to the precursors.

Synaptosomes are sealed, organized cell fragments with an intact external membrane, cytoplasm containing the full complement of glycolytic enzymes, and, usually, one or more small mitochondria. They can thus be regarded as miniature non-nucleated neurons or even as models of cells in general (Whittaker, 1968b). When warmed in a saline medium suitably fortified with metabolites and co-factors, they synthesize high-energy phosphate (Marchbanks and Whittaker, 1967; Bradford, 1969), extrude potassium (Bradford, 1969), take up sodium (Ling and Abdel-Latif, 1968), synthesize protein (Morgan and Austin, 1968), glycoprotein (Barondes, 1968), and glycolipids (S. Roseman, personal communication), and display sodium-dependent, carrier-mediated uptake of various substances: transmitters, including norepinephrine (Colburn et al., 1968; Bogdanski et al., 1968), and, under special conditions, acetylcholine (Marchbanks, 1969), amino acids (D. G. Grahame-Smith, L. Austin, personal communications), and choline (March-

FIGURE 1 Left. Portion of cortical tissue showing dendrite spine and three presynaptic nerve terminals (outlined). Right. Detached presynaptic nerve terminal (synaptosome)

banks, 1968a; Potter, 1968; Diamond and Kennedy, 1969); as a result, they should be useful source material for the isolation of carriers. For studies of membrane function, they are a useful "halfway house" between whole cells and phospholipid spherulites.

Synaptosomes may be used in various ways to enlarge our knowledge of the morphology of the terminal region. High-resolution techniques, such as negative staining, which cannot be used with intact tissue, can be applied to the synaptic region by utilizing synaptosomes and their constituent organelles (Horne and Whittaker, 1962). Portions of postsynaptic membranes often remain adherent to the periphery of synaptosomes, which shows that the cleft contains an effective adhesive binding the presynaptic and postsynaptic membranes together. Other forms of controlled damage to the terminal region give additional information. Thus on hypo-osmotic lysis, synaptosomes do not all disintegrate into their component parts; some hang together, appearing as clumps of synaptic vesicles and intraterminal mitochonshowing similarity of structure to terminal *in situ* and postsynaptic adhesion.

dria surrounded by broken external membranes but devoid of soluble cytoplasmic constituents (Johnson and Whittaker, 1963; Whittaker et al., 1964), suggesting that the cytoplasm contains a gel-like material. In negative staining, this material resembles a polysaccharide such as Ficoll (observations of V. P. Whittaker reported in part by Hosie, 1965). Quantitative morphological studies can be carried out with synaptosomes (Clementi et al., 1966; Whittaker and Sheridan, 1965) more easily than with whole tissue; synaptosome fractions provide randomized samples of nerve terminals that could overcome sampling problems in evaluating the degree of synaptic connection in normal and pathological development.

Limitations of the synaptosome technique

The main limitation of the synaptosome technique is that a synaptosome preparation is a mixed population of nerve endings utilizing different transmitters. In special cases, however, specific types of terminal can be separated, e.g., the mossy-fiber and parallel-fiber terminals from the cerebellar cortex (Israël and Whittaker, 1965; Johnston and Larramendi, 1968; Del Cerro et al., 1969). There is also the possibility of using peripheral tissue with a single type of innervation, such as electric organ, with its purely cholinergic innervation (Sheridan et al., 1966; Israël et al., 1968). Unfortunately, in peripheral tissues, the mechanical factors favoring the "pinching-off" of nerve terminals are not present, and the best that can be done so far is to isolate vesicles. This limits the possibility of studying the organization of the whole terminal region. In mammalian peripheral tissues, an additional problem is the small proportion of the whole tissue represented by nerve endings and the consequent low concentration of transmitter.

Another problem is the amount of material that can be processed. Terminals represent only 2 to 3 per cent of brain tissue; synaptic vesicles, only about 0.1 per cent (Whittaker, 1968a). Thus, when one is working with normal centrifuge equipment and the 1 to 10 grams of brain tissue that can be processed in a single run, the yield of material is too small for many purposes, especially if quite homogeneous preparations are required. There is, however, no difficulty in the scaling up of preparations with the zonal rotors now commercially available (Figure 2). At the other end of the scale, fractionation with 1 to 10 milligrams of tissue is feasible (V. P. Whittaker, unpublished observations; Giacobini, 1969), provided sufficiently sensitive analytical methods are available. Such scaled-down operations will be useful in studies of axonal flow and for work on small, relatively homogeneous samples of nervous tissue, such as sympathetic ganglia.

Yet another problem is the sensitivity of synaptosomes to autolysis and mechanical damage. They are much less stable than mitochondria, a fact that may partially explain why they remained undiscovered for so long. If one works at all times under conditions of good refrigeration (preferably in a cold laboratory), however, synaptosomes survive well, and short-term metabolic experiments at 25 to 37° C can be performed on them. There is some evidence that synaptosomes separated in Ficoll density gradients are more stable than those prepared in hyperosmotic sucrose, although they are more contaminated by other structures because of the absence of differential osmotic dehydration. Certain polymers (Ficoll, dextran, polyvinylpyrollidine) are thought to exert a stabilizing effect on cell membranes. However, critical comparisons between synaptosomes prepared in sucrose and Ficoll have not been made, and the latter are metabolically competent. Synaptosomes are considerably more sensitive to damage during fixation, staining, and embedding for electron microscopy than are other subcellular structures. Certain histochemical techniques (e.g., cholinesterase staining) do not give good results with synaptosomes, presumably because of the greater opportunities for the diffusion of products in a pellet compared with that in a whole-tissue block (L. L. Ross, personal communication), but others (e.g., fluorescence histochemistry of monoamines) work well (Masuoka, 1965).

The sensitivity of synaptosomes to autolysis may be the consequence of a local concentration of proteolytic enzymes in the terminal region concerned with the disassembly of proteins arriving there as a result of axoplasmic flow.

A comprehensive account of work on synaptosomes would be out of place here; for further information, the

FIGURE 2 Separation of mitochondria (black peak at right) and synaptosomes (central black peak) from myelin and glial fragments (peak at left) from guinea-pig cortex in a 660 ml zonal rotor. Abbreviations: ACh, acetylcholine, a synaptosomal marker; BuChE, butyrylcholinesterase, a

putative glial marker; MHL, malate hydrolyase, a mitochondrial marker. Note coincidence of potassium peak (K) and shoulder of mitochondrial marker with synaptosomes. Amount of brain processed was about 20 g.

reader is referred to recent reviews and printed lectures (Whittaker, 1965; Whittaker, 1969a, 1969b, 1969c, 1969d; Marchbanks and Whittaker, 1969). Attention is confined here to current work in my laboratory on the organization of the cholinergic terminal.

Organization of the cholinergic terminal

LOCALIZATION OF ACETYLCHOLINE It has long been known that only about 25 per cent of the acetylcholine of forebrain can be extracted when the tissue is homogenized or comminuted in iso-osmotic aqueous media (e.g., 0.32 M sucrose) containing a cholinesterase inhibitor (for references, see Hebb and Whittaker, 1958). This acetylcholine is pharmacologically detectable, without further treatment, in the homogenate or in a high-speed supernatant fraction derived from it and is readily hydrolyzed by cholinesterases; the presence of a cholinesterase inhibitor in the suspension medium is necessary to stabilize it.

The remainder of the tissue acetylcholine is particlebound, resistant to attack by cholinesterases, and undetectable pharmacologically unless first liberated from the particulate material by a variety of treatments that have in common their ability to destroy the integrity of lipoprotein membrane structures. A series of papers (Hebb and Whittaker, 1958; Whittaker, 1959, 1961; Gray and Whittaker, 1960, 1962) established that the "particle" containing the bound acetylcholine is the synaptosome. Bound acetylcholine represents the presynaptic store of acetylcholine in the tissue and owes its existence in homogenates and fractions derived therefrom to the ease with which presynaptic nerve terminals are detached to form synaptosomes. The free acetylcholine must originate either from synaptosomes disrupted during the initial homogenization or from cholinergic axons and cell bodies. The latter origin is more likely, because nerve terminals appear to be converted in high yield to synaptosomes (Clementi et al., 1966), and there are very few vesicles in forebrain homogenates.

Other work (Hebb and Whittaker, 1958; Whittaker, 1959; Whittaker et al., 1964; Whittaker and Sheridan, 1965) established that bound (i.e., synaptosomal) acetylcholine consists of more than one fraction. Disrupting of synaptosomes by suspension in hypo-osmotic solutions causes the release of 40 to 60 per cent of the bound acetylcholine (the "labile-bound" fraction); a variety of evidence (Marchbanks, 1968b) suggests that this is acetylcholine sequestered within the soluble cytoplasm of the synaptosome and bound only in the sense that the external membrane of the synaptosome constitutes a barrier to its free diffusion into the surrounding medium.

Fractionation of disrupted synaptosomes on a sucrose density gradient shows that the osmotically resistant ("stablebound") fraction of synaptosomal acetylcholine is associated with vesicles; the observed amount per cholinergic

vesicle could be accounted for if the vesicle core is assumed to be filled with an approximately iso-osmotic solution of acetylcholine. This acetylcholine is released by osmotic stresses greater than the stress originally applied to the synaptosomes, suggesting that the acetylcholine is not simply adsorbed to the surface of the vesicle. The actual state of acetylcholine within the vesicle is, however, unknown. It may well be bound to a macromolecule analogous to chromogranin, the protein-binding norepinephrine in adrenergic nerve terminals and chromaffin granules. If so, the greater stability of synaptic vesicles to osmotic shock, compared to that of synaptosomes, might be simply a function of the greater ratio of surface area to volume of the vesicles, also compared to synaptosomes. This greater ratio would permit more rapid equilibration with media of lowered osmotic pressure.

The amount of acetylcholine per cholinergic vesicle (estimated to be about 2000; Whittaker and Sheridan, 1965; Whittaker, 1966a) is consistent with the requirements of the vesicle hypothesis. However, as we shall see, the vesicular pool of acetylcholine turns over more slowly than can account for the specific radioactivity of acetylcholine released from cholinergic terminals labeled with radioactive choline, suggesting an involvement of nonvesicular acetylcholine in transmitter release.

Attempts have been made recently (Chakrin and Whittaker, 1969; Richter and Marchbanks, 1969) to find out by means of radioactive precursors, whether the three fractions of brain acetylcholine simply originate from the redistribution of acetylcholine from a single pool during homogenization or pre-exist in the original tissue. Radioactive choline is incorporated into brain-cortex acetylcholine by intracortical injection in vivo or by the incubation of cortical tissue blocks in a physiological saline medium containing the precursor; the tissue is then homogenized, and synaptosomes and synaptic vesicles are isolated and extracted in the usual way. The extracts contain other radioactive products in addition to acetylcholine (mainly choline and phosphorylcholine). These are removed by submitting the extracts to column or thin-layer chromatography. A liquid ion-exchange extraction method developed by Fonnum (1969) has proved useful for separating choline derivatives from other constituents in the tissue extract. The identity of the radioactive acetylcholine that is isolated is checked by treating a sample of extract with acetylcholinesterase; any cholinesterase-resistant counts appearing in the acetylcholine region are deducted.

The results show (Table I) that vesicular acetylcholine is less labeled, at one hour, than synaptosomal cytoplasmic acetylcholine, and that free acetylcholine is even less labeled. This indicates that the various pools are turning over at different rates and do not result from the redistribution of a single pool during homogenization. RELATION OF SUBCELLULAR ACETYLCHOLINE TO RE-LEASED ACETYLCHOLINE Both types of preparation release acetylcholine spontaneously and, at a greatly increased rate, on stimulation. In the cortical preparation, the released, radioactive acetylcholine is collected by sealing a small sleeve or cup onto the surface of the cortex (Mitchell, 1966); acetylcholine released from the subjacent tissue diffuses into eserinized Ringer solution that has been placed in the cup. Cholinergic afferents can be stimulated by suitably placed electrodes. In the experiments with incubated blocks of cortical tissue, stimulation is brought about by 33 millimolar potassium.

Both types of preparation show a phenomenon that is difficult to explain on the basis of current ideas about transmitter release. The specific radioactivity of the acetylcholine released during stimulation and, still more, that of the acetylcholine released under resting conditions, are considerably higher than that of vesicular acetylcholine. The specific radioactivity of the acetylcholine released under resting conditions is, in fact, higher than *any* subcellular fraction isolated by current techniques. The fall in specific activity that takes place on stimulation may result from the augmentation of the resting release by acetylcholine derived from less radioactive stores, e.g., vesicles.

The identity of the rapidly labeled pool is obscure. It may represent a population of metabolically active but labile vesicles from which acetylcholine is preferentially released but which does not survive isolation. Or it may represent acetylcholine synthesized from choline and taken up from the medium before this has had time to mix completely with endogenous choline; Kety's concept (this volume) of a preferentially released pool of transmitter adsorbed onto the external membrane may be relevant here.

LOCALIZATION OF CHOLINE ACETYLTRANSFERASE Acetylcholine is synthesized by an enzyme, choline acetyltransferase, that catalyzes the transfer on an acetyl group

TABLE I

Specific radioactivity of acetylcholine of subcellular fractions from guinea-pig brain after intracortical injection of [N-Me-³H] choline given one hour previously

Fraction	Specific Radioad Acetylcholine in (Mean ± S	tivity of Fraction .D.)
	Disintegration per Minute per Picomole	As % of
Synaptosomes	7.1 ± 1.8	100
Vesicles	4.6 ± 0.3	66 ± 5
High-speed supernatant*	2.5 ± 0.1	36 ± 1

* Eserine present in homogenate.

from acetylcoenzyme A to choline. The subcellular distribution of this enzyme closely resembles acetylcholine itself, as far as the primary fractions are concerned. As is acetylcholine, about 25 per cent of the homogenate enzyme is in a free, fully active, nonparticulate form; the remainder is synaptosomal. Within the synaptosome, there is probably only one form-cytoplasmic. Evidence to the contrary (McCaman et al., 1965) overlooked the fact (Fonnum, 1967) that at the low ionic strengths of hypo-osmotic synaptosome suspensions, the enzyme tends to be adsorbed onto external membrane fragments, and that such fragments heavily contaminate the vesicle fraction used by these authors. The degree of binding of the enzyme to the external membrane as a function of ionic strength varies from one species to another, increasing from pigeon to guinea pig to rat to rabbit. The cat and sheep enzymes are also relatively strongly adsorbed. At the presumed ionic concentration of the synaptosome cytoplasm, the enzyme, in all species, is largely in the soluble form. However, a small amount of adsorption onto the external membrane in vivo cannot be excluded, and this, rather than extracellular enzyme, might be responsible for the pool of acetylcholine that turns over rapidly and is involved in resting transmitter release.

The mechanism whereby acetylcholine synthesized in the cytoplasm is transferred to the vesicles remains obscure. Possibly the system resembles that of the Ca²⁺-accumulating vesicles derived from the pinching-off of the sarco-tubular system of muscle (Makinose and Hasselbach, 1963), but all attempts to detect an acetylcholine-stimulated adenosine triphosphatase or ATP-stimulated radioactive acetylcholine exchange with vesicle preparations have so far failed.

LOCALIZATION OF ACETYLCHOLINESTERASE The third characteristic component of cholinergic neurons, acetylcholinesterase, has a more complex subcellular distribution than either acetylcholine or choline acetyltransferase. In this case, fortunately, a specific histochemical method exists; applied at the electron-microscope level, it greatly assists in clarifying the otherwise somewhat confusing subcellular distribution data.

The fraction with the highest *specific* activity is the microsomal fraction. Electron-microscope studies (Lewis and Shute, 1966) show that the lumen of the endoplasmic reticulum of cholinergic neurons stained strongly for reaction products; fragments of this will be recovered in the microsome fraction. On the other hand, there are appreciable amounts of the enzyme in the myelin and synaptosome fractions; on subfractionating synaptosomes, the enzyme is localized in the external membrane fraction (Whittaker et al., 1964). Properly prepared vesicles (Figure 3) free from external membrane fragments (but not those prepared by the method of McCaman et al., 1965) have negligible

FIGURE 3 Isolated synaptic vesicles prepared by density-gradient centrifuging. Note absence of contaminating membranes.

amounts of esterase activity. These observations agree with the morphological findings: the enzyme is localized in the plasma membrane underneath the myelin sheath and, in high concentration, on the external membrane of the cholinergic nerve terminal.

The coexistence of cytoplasmic acetylcholine and acetylcholinesterase in the synaptosome seems less paradoxical if it is assumed that the functional groups of the enzyme face outward and are therefore not accessible to endogenous acetylcholine. There is some evidence for this: on standing, endogenous acetylcholine declines at a rate determined by diffusion through the external membrane, and far more slowly than a similar concentration of acetylcholine applied externally.

In conclusion, the discovery of synaptosomes has opened up a useful, new, and more direct approach to many problems of synaptic function. Much work must be done, however, before the mechanisms of storage and release of chemical transmitters are fully understood.

Neurotransmitters, Neurohormones, and Other Small Molecules in Neurons

LESLIE L. IVERSEN

NEURONS CONTAIN a very large number of substances of low molecular weight, but most of these, such as the sugars, amino acids, fatty acids, nucleotides, and coenzymes involved in intermediary energy metabolism and other metabolic pathways, are universal components of living tissues and have no special relevance for neuronal function. I have chosen to discuss a few aspects of certain substances that are intimately involved in the functional properties of neurons. After a brief description of a group of organic anions that play an important role in maintaining the electrical polarization of the neuronal membrane, the rest of this chapter is devoted to a description of neurotransmitters and other neurosecretory products. All neurons are secretory cells, in the sense that they release a neurotransmitter or a neurohormone. Different types of neuron often have obvious, morphologically distinguishing features, but they may be differentiated equally characteristically according to the particular neurotransmitter or neurohormone they manufacture and secrete. This chemical individuality of neurons can be exploited by appropriate histochemical techniques as a powerful tool for mapping the anatomical distribution of a particular neuronal type in the heterogeneous population of the nervous system.

This chapter necessarily suffers from major omissions; for instance, space does not allow the inclusion of any description of important groups of substances, such as the carbohydrates involved in neuronal glycoproteins and gangliosides (Barondes, this volume), or the neuronal lipids.

Organic anions

The presence of organic anions in the axoplasm of neurons is an important feature in the ionic balance leading to the establishment of the resting membrane potential across

LESLIE L. IVERSEN Department of Pharmacology, University of Cambridge, Cambridge, England

the neuronal membrane. From the studies of Schmitt and his coworkers on the ionic composition of the axoplasm of squid giant nerve fibers and lobster nerves, it was apparent that the concentration of inorganic anions, such as chloride, in the axoplasm was considerably lower than the total concentration of inorganic cation, indicating that a considerable "anion deficit" existed in axoplasm (Bear and Schmitt, 1939). This deficit has since been accounted for by various organic anions that are present in high concentrations in axoplasm. Koechlin (1955), for instance, showed that, in the axoplasm of squid giant fibers, the major organic anion is isethionic acid (2-hydroxyethane sulphonic acid), which is present in very high concentrations, accounting for some 20 per cent of the dry weight of axoplasm (Table I). In other species, various other organic anions may serve a similar role-for example, aspartic acid, glutamic acid, and Nacetyl aspartic acid (Figure 1). N-acetyl aspartic acid is thought to be particularly important in this respect in mammalian brain, in which it occurs in some abundance (Tallan, 1957).

Neurotransmitter substances

IDENTITY AND OCCURRENCE IN VARIOUS TISSUES Table II lists those compounds known to act as neurotransmitters and the other compounds that probably fill this role. The Table describes, for each compound, the particular synapses for which the most extensive evidence is available. A discussion of the criteria used to establish the identity of neurotransmitter substances, or the detailed evidence available for each of the compounds in the Table are not possible here; these points are covered in the references cited. Although it seems likely that at least 10 different neurotransmitters exist, only three substances have been conclusively established as

FIGURE 1 Structures of some organic anions found in axoplasm.

transmitters to date: acetylcholine (ACh), norepinephrine (NE), and γ -aminobutyric acid (GABA). Apart from these three compounds, glutamate is a probable candidate as the excitatory transmitter released at insect neuromuscular junctions (Usherwood et al., 1968), and 5-hydroxytryptamine (5-HT, or serotonin) as the cardiac excitatory transmitter in molluscan heart (Welsh, 1957). GABA, glycine, and dopamine are possible inhibitory transmitters in the mammalian CNS (see Table II). The list of neurotransmitters and probable candidates for this role includes a diversity of chemical structures (Figure 2), but all the substances are small diffusible molecules (molecular weight <300), and there is a preponderance of amines.

Many of the compounds listed in Table II are found throughout the animal kingdom. In particular, the amines (NE, dopamine, 5-HT, and ACh) occur in considerable abundance in many invertebrate nervous systems (Cottrell and Laverack, 1968), but are found only in relatively low concentrations in the mammalian CNS, perhaps reflecting the prominence of other, more recently evolved, transmitter systems in higher animals. Few generalizations can be made about the physiological functions of the various transmitters. ACh may serve both as an excitatory and as an inhibitory transmitter at different synapses in the same organism, and the same applies to NE. Furthermore, the same physiological function may be served by different transmitters in different species, for instance, the excitatory innervation of vertebrate skeletal muscle is exclusively cholinergic, but this function may be served by L-glutamate in crustaceans or by 5-HT in annelids. Some compounds appear to be almost exclusively inhibitory or excitatory in their trans-

 Current list of transmitter substances and probable candidates

mitter role; thus, GABA and dopamine are usually found to produce inhibitory effects, and glutamate to produce excitatory effects. Excitatory effects for GABA and dopamine and inhibitory effects for glutamate have, however, been reported in some cells of molluscan ganglia (Tauc, 1967; Gerschenfeld and Lasansky, 1964; Kerkut and Walker, 1962).

It is clear that the nature of the effect produced by a particular transmitter substance is determined largely by the type of postsynaptic receptor with which the transmitter interacts. Several different types of receptor probably exist for most transmitters; for instance, at least three receptor types are known for acetylcholine in mammalian systems (Table II), and further types of ACh receptors have been described in invertebrates (Tauc, 1967). Two cell types, termed D and H, have been described in molluscan ganglia. Both are depolarized or hyperpolarized respectively by ACh. Although the receptors involved in these two cell types are distinguishable by pharmacological criteria (hexamethonium blocks ACh effects on D cells but not on H cells), the effect of ACh on both types of cell appears to be an increased permeability to chloride ions (Tauc, 1967). The factor that determines the nature of the response appears to be the intracellular chloride-ion concentration of the two types of cell—this has been measured as 11.2 ± 0.6 millimolar for H cells and 24.7 \pm 0.8 millimolar for D cells. In the D cells, therefore, the chloride equilibrium potential is less negative than the resting potential, so that ACh produces a depolarization, whereas the converse holds for the H cells (Kerkut and Meech, 1966). Even the same transmitter acting on the same receptor type may produce excitatory or inhibitory effects in different tissues. Thus, NE acting on " β -adrenergic" and " α -adrenergic" receptors produces excitatory effects on cardiac and many smooth muscles, but

FIGURE 2 Structures of some neurotransmitters and putative neurotransmitters.

produces inhibitory effects on intestinal smooth muscle (Bülbring and Tomita, 1969).

As the number of chemically transmitting synapses with identified transmitters is increased, it may be necessary to consider some formal system of nomenclature to describe the many types of synapse that exist. The currently accepted terms "cholinergic" and "adrenergic" (Dale, 1934) are now seen to be somewhat lacking in precision. The term "cholinergic," for example, does not distinguish between the various types of synapse in which ACh is the transmitter. The term "adrenergic" does not allow a distinction to be made between the various types of synapse in which NE, dopamine, or adrenalin is a transmitter. For a complete description of a particular synapse, a formal system of nomenclature should perhaps describe (1) the transmitter released from the presynaptic nerve terminal; (2) the nature of the effect produced in the postsynaptic cell (i.e., excitatory or inhibitory); and (3) the type of receptor involved (usually characterized by a specific antagonist drug). The vertebrate neuromuscular junction would thus be described as "acetylcholine, excitatory, d-tubocurarine," the synapses in autonomic ganglia as "acetylcholine, excitatory, hexamethonium," and so on. These might be abbreviated, for example, as ACh-E-C and ACh-E-H, respectively, and so on.

The points outlined above emphasize that the postsynaptic receptor sites with which transmitters interact are of great importance in determining the biological activity of these substances. This is further emphasized when it is realized that the neurotransmitter substances are by no means unique components of nervous tissues. ACh, for example, is found in certain non-neuronal tissues, notably in large amounts in mammalian placenta-which appears to lack any cholinergic innervation (Hebb, 1957). The catecholamines are found in glandular chromaffin cells in the adrenal medulla and in other mammalian tissues (Coupland, 1965); dopamine is present in a specialized form of mast cell in ruminant mammals (Bertler et al., 1959). Serotonin has a particularly ubiquitous distribution; large amounts of this substance are present in enterochromaffin cells of the vertebrate intestinal mucosa, blood platelets, mast cells, certain exocrine and endocrine glandular cells, pinealocytes, frog skin, fish spermatophores, and many insect and molluscan venoms (Erspamer, 1966). The catecholamines and 5-HT are even found in substantial amounts in certain microorganisms and in some plant tissues (Erspamer, 1966). The reductio ad absurdum for the notion that neurotransmitters are uniquely neuronal components is seen with the putative transmitters glycine and L-glutamate, which are found in the free amino-acid pool of every living cell as precursors for protein synthesis. The universal occurrence of glycine and glutamate might appear to argue against the view that these substances could act as neurotransmitters, but although such an argument has a certain emotional impact, it is clear that no transmitter substance has been shown to have a uniquely neuronal localization. The necessary specificity for chemical transmission is determined not by the occurrence of unique chemicals, but rather by the existence within a given neuron of specialized mechanisms for the manufacture, storage, and release of a particular substance, and by the occurrence of specific receptor sites on the postsynaptic cell. Those sites recognize and respond to the released chemical in a characteristic manner. On this basis, almost any small diffusible substance could act as a transmitter, which does not in any way preclude that substance from serving various other physiological or metabolic functions.

THE BIOSYNTHESIS OF NEUROTRANSMITTERS The biosynthetic pathways for ACh, the catecholamines, 5-HT, and GABA are outlined in Figure 3 and are not described in

FIGURE 3 Biosynthetic pathways for some neurotransmitters.

detail here. Certain features of transmitter biosynthesis, however, appear to be common to all these systems.

1. Transmitter biosynthesis takes place within the neuron that secretes that transmitter, and the precursor for this biosynthesis is a substance found in some abundance in plasma or other extracellular fluids (choline, L-tyrosine, L-tryptophan, or L-glutamate). Each type of neuron probably possesses a specific transport mechanism to mediate the uptake of the appropriate precursor from the extracellular fluid into the neuron.

2. The enzymes responsible for the biosynthesis of a particular transmitter are found throughout all regions of the neurons that contain that transmitter, i.e., in cell body, preterminal axon, and nerve terminals. The major portion of the biosynthetic enzymes, however, is found in the region of the nerve terminals. Thus, in brain homogenates, most of the choline acetylase, tyrosine hydroxylase, tryptophan hydroxylase, and glutamic decarboxylase activities are recovered in nerve-ending particles or "synaptosomes" (Whittaker, 1965, and this volume). The concentration of the transmitter substance itself in different regions of the neuron often shows a similar distribution, with small amounts occurring in all regions of the cell, but with the highest concentrations in the nerve terminals (Figure 4).

3. In several cases, there is evidence that the rate of transmitter biosynthesis may be controlled by a negative-feedback inhibition exerted by the end product on an early step in the biosynthetic pathway. Thus, in vitro studies have shown that acetylcholine inhibits choline acetylase (Potter et al., 1968), norepinephrine and dopamine inhibit tyrosine hydroxylase (Udenfriend, 1968), and, in crustacean inhibitory neurons, γ -aminobutyric acid inhibits glutamic decarboxylase (Kravitz et al., 1965). These may constitute simple mechanisms by which the rate of transmitter biosynthesis is geared to the rate of utilization. It has been shown that the rate of transmitter synthesis in adrenergic and cholinergic nerves is increased during nerve activity, although the magnitude of this increase seems to be somewhat greater in cholinergic neurons, in which the rate of ACh synthesis may increase by more than seven-fold during nerve stimulation, than in adrenergic nerves, in which increases of threefold in the rate of NE synthesis have been found (Birks and MacIntosh, 1961; Udenfriend, 1968). Feedback inhibition may not be the only mechanism involved in regulating the rate of transmitter synthesis; the synthesis of GABA in mammalian brain, for example, is not subject to feedback inhibition by the product, but is sensitive to inhibition by such anions as chloride (Roberts and Kuriyama, 1968). The synthesis of ACh may also be influenced by the ionic composition of the axoplasm, and, as the synthetic reaction is reversible, may also be governed by simple mass-action effects (Potter et al., 1968).

4. It seems likely that transmitter biosynthesis takes place most rapidly in nerve terminals, which contain the bulk of the biosynthetic enzymes. Indeed, it is difficult to imagine how any mechanism involving a remote synthesis of transmitter could meet the rapid demands for newly synthesized transmitter at the nerve terminal during sustained nerve activity. Estimates of the amount of ACh or NE released by a single nerve impulse in both cholinergic and adrenergic nerves indicate that the total reserves of transmitter stored in the terminals of either type of neuron are sufficient for only about 10,000 impulses, and, because only a portion of the total store is available for release, the functional reserves are sufficient for only a few minutes of sustained activity (Birks and MacIntosh, 1961; Stjärne et al., 1969). In the cholinergic nerves to the cat superior cervical ganglion, for example, the amount of ACh released during a 60-minute period of stimulation at a frequency of 20 impulses per second is equivalent to more than five times the total content of ACh in the ganglion (Birks and MacIntosh, 1961). Furthermore, normal rates of NE biosynthesis can be maintained for long periods in isolated organs, such as the heart or spleen, even though only the adrenergic terminal innervation is preserved in such preparations (Levitt et al., 1965). On the other hand, the manufacture of the enzymes themselves probably occurs exclusively in the perikaryal region of the neuron, which contains the nucleus and most of the mechanisms involved in protein synthesis; the possibility of enzyme synthesis by mitochondria at endings has been considered, but its role is not clear (Lehninger, this volume). There is, furthermore, a continuous flow of newly synthe-

FIGURE 4 Schematic illustration of the intraneuronal distribution of norepinephrine in a sympathetic adrenergic neuron of the rat or cat. (Reproduced with permission from Dahlström, 1967; Dahlström and Häggendal, 1966; Dahlström et al., 1966; Norberg and Hamberger, 1964.)

sized macromolecular components from the cell body along the axon toward the terminal regions of the neuron (Weiss, this volume; Davison, this volume), so that the biosynthetic machinery at the nerve terminal is continuously renewed. The biosynthetic enzymes are made in the cell body region of the neuron and must pass down the axon to the terminal regions, which probably explains why the enzymes are found in all regions of the neuron, and may also account for the presence of the transmitter substance in the cell body and axon, although only that in the terminals is functional.

Substances and structures involved in transmitter storage, such as the macromolecular components of synaptic vesicles, are also continuously replenished by perikaryal synthesis and axoplasmic flow. Studies of the rate of transport of adrenergic vesicles (detected by virtue of their NE content) down sympathetic nerve trunks (Dahlström and Häggendal, 1966, 1967) have indicated that the average lifetime of an adrenergic vesicle in the terminals of such neurons is between 35 and 70 days (Figure 4). This finding is of considerable interest, for the value of 35 to 70 days is much longer than the average lifetime (approximately 12 hours) of a norepinephrine molecule in the adrenergic nerve terminals. It follows that the vesicle stores of NE must be constantly replenished by a biosynthesis of NE in the nerve terminals, and that the amounts of NE which travel down the axon in association with preformed adrenergic vesicles cannot make any substantial contribution to the functional pool of NE in the terminal stores. This conclusion was also reached from the studies of Geffen and Rush (1968) on the rate of transport of NE down sympathetic nerve fibers. The concept of synaptic vesicles as re-usable storage packages is also in accord with current views concerning the mechanisms involved in transmitter release, which are discussed below.

A question of great interest is whether the rate of synthesis and axonal transport of the biosynthetic enzymes and storage-vesicle components is controlled by nerve activity. Although very little information is available on this point, recent reports indicate that the amount of tyrosine hydroxylase activity in adrenergic nerves or in adrenal medullary cells increases when these cells are subjected to stimulation (Viveros et al., 1969; Weiner and Rabadjija, 1968; Mueller et al., 1969). These findings may, perhaps, open new vistas in one of the most exciting directions for neurobiology, namely, the description of mechanisms by which neuronal activity can modify synaptic function.

TRANSMITTER RELEASE When an action potential reaches the terminal regions of a neuron, the accompanying depo-

larization is rapidly followed by a release of transmitter substance into the synaptic cleft. Transmitter release takes place with a finite delay which has been measured as between 0.3 and 0.5 milliseconds for the release of ACh at the vertebrate neuromuscular junction (Katz and Miledi, 1965). The precise mechanisms involved in transmitter release are not yet known, but research on this problem and the general area of stimulus-secretion coupling is now proceeding rapidly. It seems likely that transmitter release at all chemically transmitting synapses may, as in the case of the neuromuscular junction, be characteristically of a quantal nature, i.e., the amount of transmitter released from the presynaptic nerve terminal is not continuously graded, but occurs as multiples of a basic quantum amount (Katz, 1966). In the absence of nerve activity, random spontaneous "miniature endplate potentials" (m.e.p.p.s.) were recorded from the innervated muscle fibers when recording electrodes were inserted into the muscle at a point close to the motor endplate. The m.e.p.p.s. appeared to be due to a spontaneous release of ACh from the nerve terminals, as they were blocked by anticholinergic drugs and prolonged by anticholinesterases. Furthermore, the amplitude of the m.e.p.p.s. was remarkably constant, indicating the quantal nature of the release. It could, furthermore, be shown that the release of ACh evoked by nerve stimulation was composed of a burst of some 300 quanta per nerve impulse. This was most convincingly demonstrated in experiments in which stimulation was applied to preparations in a low-calcium or high-magnesium medium, in which the amount of ACh release was much less than that normally found; under such conditions, the amplitude of the evoked potential recorded from the muscle cells during repeated stimulations showed a multimodal frequency distribution, with peaks occurring at one, two, three, and four times the mean amplitude of the spontaneous m.e.p.p.s. (Figure 5) (Boyd and Martin, 1956). Spontaneous miniature synaptic potentials have subsequently been recorded from other noncholinergic synapses: from adrenergic synapses on smooth muscle (Burnstock and Holman, 1966), from crayfish and insect neuromuscular junctions (Dudel and Orkand, 1960; Usherwood, 1963), and from squid giant fiber synapses (Miledi, 1966). It is now generally accepted, although not definitively proved, that the quantal release of transmitter substances is related to the storage of the transmitters in discrete packages in the form of synaptic vesicles, 300 to 500 Å in diameter, which feature prominently in the morphological appearance of all chemically transmitting synapses. For ACh, NE, dopamine, and 5-HT there is evidence that, within the nerve terminals containing these substances, the transmitters are present in high concentrations in the vesicle storage sites (Whittaker, 1965, and this volume). The possibility that they may be present in appreciable amounts in cytoplasmic (nonvesicle) solution is shown by Whittaker (this volume) for ACh and by Kety (this volume), who postulates substantial storage in the presynaptic membrane. These newer data may have an important influence on our theories of quantal release, storage, and release mechanisms.

If the concept of quantal release is accepted, the problem of the mechanism of release becomes one of explaining how the transmitter substance is transferred from the storage site within a membrane-bound vesicle to the extracellular fluid outside the axonal membrane. As yet, there is very little detailed evidence concerning the mechanisms. Transmitter release does not involve the membrane systems which are responsible for the ionic permeability changes associated with the conduction of the nerve action potential; m.e.p.p.s. and evoked transmitter release can occur in the presence of tetrodotoxin, which specifically blocks the action potential mechanisms (Katz and Miledi, 1965).

The transmitter release process seems likely to prove similar to that in other secretory systems, such as those in the secretion of hormones or other products from glandular tissues. The secretory process in nerves and glandular tissues shows an absolute dependence on the presence of calcium ions in the external fluid surrounding the secretory tissue; glandular secretion is, furthermore, known to involve an inward movement of calcium into the secretory cell. Both neurotransmission and glandular secretion can also be suppressed by elevated magnesium concentrations. The secretory products of glandular tissues are stored in packets, in the form of secretory granules (1000 to 3000 Å in diameter). A glandular secretory system which has been extensively studied is that involved in the release of catecholamines (NE and adrenalin) from the chromaffin cells of the adrenal medulla in response to splanchnic-nerve stimulation or to applied ACh (for reviews, see Douglas, 1968; Smith, 1968). The secretory cells of the adrenal medulla are homologous with adrenergic neurons, and the two types of cell resemble each other in many ways. The release of catecholamines from adrenergic nerves and from the medulla is stimulated by similar secretogogues (ACh, nicotine, DMPP [1, 1dimethyl-4-phenylpiperazinium iodide], barium); both processes are calcium-dependent. In the medullary cells, the catecholamines are stored in dense-core particles that are similar to, but larger (800 to 1200 Å) than, adrenergic synaptic vesicles.

In both types of storage particle, the amines appear to be bound by a mechanism that causes the formation of a complex with adenosine triphosphate (ATP) or other adenine nucleotide; ATP is present in each case in a stoichiometric ratio of 1 mole of ATP for each 4 moles of catecholamine (Hillarp and Thieme, 1959; Stjärne, 1964). In addition, both medullary particles and adrenergic vesicles contain the enzyme dopamine- β -hydroxylase, which catalyzes the terminal step in the NE biosynthetic pathway (Figure 3); in medullary particles, the enzyme is partly bound to the

FIGURE 5 Histograms of endplate potentials (e.p.p.) and spontaneous amplitude distribution in a cat muscle fiber in which neuromuscular transmission was blocked by increasing the magnesium concentration of the Krebs solution to 12.5 mM. Peaks in e.p.p. amplitude distribution occur at one, two, three, and four times the mean amplitude of the

spontaneous miniature potentials. Gaussian curve is fitted to spontaneous potential distribution and used for calculating theoretical distribution of e.p.p. (continous curve). Arrows indicate expected number of failures of response to nerve stimuli. (From Boyd and Martin, 1956.)

membranes of the storage particles and is partly in free solution within the particles (Viveros et al., 1969). A group of soluble proteins, known collectively as the chromogranins, has also been described in the purified storage particles from the adrenal medulla. The major component of the chromogranins has been isolated and purified (Smith and Winkler, 1967) and a sensitive immunological assay has been developed (Sage et al., 1967). This component, chromogranin A, is a protein of 77,000 molecular weight and is unusally rich in acidic amino-acid residues.

When the adrenal medulla is stimulated to secrete catecholamines, all the soluble contents of the storage particles appear to be discharged to the exterior of the cell. Chromogranin A, and the other chromogranins, ATP, and dopamine- β -hydroxylase have all been detected in the perfusate from stimulated adrenal glands (see Kirshner et al., 1967; Smith, 1968; Douglas, 1968; Viveros et al., 1969). Furthermore, the ratios of ATP and chromogranin A to catecholamine in the released material are similar to the ratios found for these components in the intact storage particles (Table III). On the other hand, insoluble components associated with the membranes of the medullary storage particles (lysolecithin, bound dopamine- β -hydroxylase) are not released, nor is there any detectable release of soluble components of the cytoplasm of the medullary cells (lactic dehydrogenase, phenylethanolamine N-methyl transferase). These results thus favor a mechanism of release in which all the soluble contents of the particles are discharged to the exterior, by a process of reverse pinocytosis or "exocytosis" (Figure 6). Such a mechanism was also suggested on the basis of morphological studies of adrenal medullary tissue after intense secretory activity, in which empty storage

FIGURE 6 Diagrammatic illustration of the principle of secretion by exocytosis.

particles were described (de Robertis, 1964). Recently, Poisner and Trifaró (1967) proposed a detailed model of exocytosis in the adrenal medulla that incorporates much of the curently available experimental evidence.

Far less experimental evidence is available concerning the mechanisms of neurotransmitter release, largely because of the technical difficulties involved in measuring the much smaller amounts of material released from nerve terminals as opposed to glandular tissues. Recent reports indicate, however, that a protein immunologically similar to chromogranin A is found in adrenergic vesicles (Banks et al., 1969), and that this protein is present in sympathetic ganglion cells and is transported down sympathetic axons (Livett et al., 1969). That a protein similar to chromogranin A may be implicated in the storage of NE in adrenergic synaptic vesicles and may be released along with NE from adrenergic nerve terminals is an attractive idea. It does, however, raise the question of how such a component could be replaced at the nerve terminals. As discussed above, it seems that most of the transmitter released from nerve terminals is synthesized locally at the terminals-this seems unlikely for a protein such as chromogranin A. If materials such as this are released from nerve terminals, it may be that special rapid-transit systems exist to convey them from the neuronal cell body to the terminal regions.

The probable application of the findings in the adrenal

medulla to neurotransmitter release mechanisms raises many interesting questions. It is by no means universally agreed that transmitter release takes place via a mechanism of exocytosis (see, for example, Robertson, this volume). If exocytosis, however, is the universal mechanism of secretion, the implication is that soluble components of synaptic vesicles other than the neurotransmitters themselves may be released along with the transmitter from nerve terminals. Indeed, in the adrenal medulla the amount of protein and ATP secreted is greater (on a weight-for-weight basis) than the amount of catecholamine released. Hitherto, attention has focused entirely on the release of transmitter substances from neurons, but the concomitant release of other substances-both low molecular and macromolecular-may also play an important role in the over-all relationship between the presynaptic neuron and the innervated tissue. For instance, there is good evidence that nerves exert longterm trophic influences on the cells they innervate, a phenomenon that has been most extensively studied in the relationship between nerve and muscle (Guth, 1968, 1969). In vertebrate striated muscle, the presence of the motor innervation influences the sensitivity of the muscle fibers to ACh, their cholinesterase content, and even the type of proteins that are synthesized by the muscle (Guth, 1968). These trophic influences depend on the presence of an intact functional innervation and are abolished if the innervation degenerates or if transmitter release is blocked with botulinum toxin. Although it has been suggested that ACh itself might be the "trophic substance" released from the nerve (Drachman, 1967), there are reasons for believing that some substance other than ACh may be responsible (Miledi, 1960). It seems possible, therefore, that the trophic substance may represent some soluble component of the synaptic vesicles that is released along with ACh, although the existence or chemical identity of such a substance is, of course, still unknown.

TRANSMITTER CATABOLISM AND INACTIVATION After the neurotransmitter has been released into the synaptic cleft and has interacted in some still-mysterious manner with the postsynaptic receptor sites, it is important that effective concentrations of transmitter should not persist in the synaptic cleft, because the information-transmitting properties of the synapse depend on the recognition by the postsynaptic cell of different firing frequencies of the presynaptic terminal. Although diffusion of the transmitter substance away from the synaptic cleft region may be sufficiently rapid in certain cases to account for the disappearance of transmitter from this region (Gerschenfeld, 1966), some specialized mechanism is thought to exist at most synapses to facilitate the rapid removal of the transmitter after its release. The classical example of such an inactivation system is the presence of acetylcholinesterase at cholinergic synapses to catalyze the rapid hydrolysis of ACh after its release from the presynaptic nerve terminals (see Kravitz, 1967). Although catabolic enzyme systems exist, however, for most of the other transmitter substances, it may be that an enzymic destruction of the transmitter substance will prove to be the exception rather than the rule. At many types of chemically transmitting synapse, the actions of the released transmitter may be terminated not by enzymic degradation but by a physical removal of the transmitter from its extracellular site of action, a process that is mediated by some specific transport system (for review, see Iversen, 1967, 1970). Such transport systems are known to exist for many of the putative transmitters (Table IV); in all cases, the systems have the properties of active-transport mechanisms (saturable, energy-dependent, sodium-dependent). The transmitter uptake systems have exceptionally high affinities for their substrates (affinity constants 0.3-30.0 micromolar) when compared with transport systems for sugars and amino acids in non-neuronal tissues (affinity constants 0.5-10.0 millimolar). There is evidence that the uptake system for catecholamines is situated in the neuronal membrane of adrenergic neurons (Iversen, 1967; this paper, Figure 7). It appears that at adrenergic synapses the transmitter substance is recaptured, in part, after its release from the nerve terminals, and that the same molecules of NE may subsequently be re-used in a further cycle of release and recapture.

In addition to transport systems, which seem likely to be important in terminating the actions of released transmitters, a catabolic enzyme, or enzymes, appropriate for the stored transmitter are known to exist in most neurons. Thus, acetylcholinesterase is not only present at the region of the synapse, but is found in all parts of the cholinergic neuron. In adrenergic neurons, the enzyme monoamine oxidase (MAO) is present, although it does not play an obvious role in adrenergic neurotransmission. Similarly, GABA-glutamate transaminase, the enzyme responsible for the degradation of GABA, is found in the axoplasm of crustacean inhibitory neurons, but does not play an obvious part in inhibitory transmission there (Kravitz et al., 1965; Kravitz, 1967). The presence of such catabolic enzymes may, however, be of some importance in determining the steady-state level of transmitter stored in these neurons. Inhibition of MAO or GABA-glutamate transaminase leads to a pronounced rise in the storage levels of catecholamines or GABA, suggesting that the catabolic enzymes may limit the normal storage levels of these transmitters.

Neurosecretion

In addition to secreting neurotransmitters, which act directly on the cells in close synaptic contact with the nerve terminals, neurons may also secrete products that act on more remote target cells. The term "neurosecretion" is now commonly used to describe the latter process (for review, see Bern and Knowles, 1966). The axon terminals of neurosecretory neurons do not form synaptic contacts, but are situated in a specialized area of the nervous system termed a "neurohemal organ," in which the materials secreted by the terminals are released into a vascular system. The secretory products ("neurohormones") of these neurons may act on remote peripheral organs through the systemic circulation (color changes in crustaceans, tanning of the integument of insects, water balance in vertebrates, growth and regeneration in annelids). Alternatively, neurohormones may act on other endocrine glands, either through the systemic circulation (ecdysiotropic brain hormone in insects, molt-inhibitory hormone of crustacean eyestalk), or through a specialized system of portal blood vessels (hypothalamic releasing factors in vertebrates). These relationships are illustrated in Figure 8. Neurosecretory systems appear to be particularly common in invertebrate nervous systems, and only a limited number are known to exist in vertebrates. Of these, the hypothalamo-neurohypophyseal system is the most important and the most thoroughly studied. This system (Figure 9) has two principal compo-

nents. First, several as-yet-unidentified neuronal systems in the hypothalamus secrete "releasing factors" into the specialized portal capillary system leading from the region of the median eminence to the anterior lobe of the pituitary gland. There are at least six such "releasing factors," each of which controls the rate of secretion of one of the endocrine hormones of the anterior pituitary (McCann and Dhariwal, 1966). Second, two groups of neurons in the anterior hypothalamus and in the supra-optic nucleus send axons to the posterior lobe of the pituitary gland. These neurons manufacture and secrete into the systemic circulation the hormones vasopressin and oxytocin. The hypothalamo-hypophyseal neurosecretory systems are of great importance in vertebrates, particularly in controlling through the anterior pituitary many of the major endocrine glands of the vertebrate body. The hypothalmic neurosecretory neurons thus act as the final common pathway in conveying information from the nervous system to the endocrine system.

The exact chemical identity of the neurohormones released by most neurosecretory neurons is unknown. In almost all cases about which information is available, however, the secretory products appear to be small polypeptides. The structure of oxytocin and vasopressin, basic cystine-containing octapeptides, are illustrated in Figure 10. Within neurosecretory neurons the neurohormones are stored in neurosecretory granules, which are usually larger than synaptic vesicles—1000 to 3000 Å in diameter. Unlike neurotransmitters, neurohormones appear to be synthesized exclusively in the cell-body region of the neuron and are then transported by axoplasmic flow to the nerve terminals. There is evidence (Douglas and Poisner, 1964) that neurosecretion involves mechanisms similar to those described for other secretory processes. Thus, the release of vasopressin from the posterior pituitary shows an absolute requirement for calcium.

FIGURE 10 Structures of the neurohormones oxytocin and vasopressin.

The parallel between neurosecretion and glandular secretion has recently been further extended by the discovery that purified neurosecretory granules from the posterior lobe of the pituitary contain two proteins—neurophysin I and neurophysin II. Each of these has a molecular weight of approximately 20,000, and they bind the neurohormones oxytocin and vasopressin. Both neurophysins form complexes with the neurohormones, which can be crystallized; there are three polypeptide binding sites per molecule of neurophysin (Hope and Dean, 1968; Hollenberg and Hope, 1968). There is also evidence that the neurophysins are released from the posterior lobe of the pituitary during secretory activity (Fawcett et al., 1968).

Conclusion—Dale's law and its implications

Dale's law (Dale, 1935) states that a given neuron secretes the same transmitter substance from all its synaptic terminals. This does not imply that the postsynaptic effects induced by activity in a single neuron are necessarily purely inhibitory or excitatory at all its terminal branches. Indeed, the elegant neurophysiological studies of Kandel et al. (1967) show that in the *Aplysia* ganglion the terminal branches of a single cholinergic interneuron produce both inhibitory and excitatory effects on different postsynaptic cells. This emphasizes again that the actions of the transmitter are determined primarily by the nature of the receptor sites with which it interacts: in this case, the different synaptic actions of ACh are caused by the existence of at least two types of postsynaptic receptor.

Dale's principle, however, is in accord with modern knowledge of transmitter biochemistry. If a single neuron secreted different transmitters from its various branches, the existence of different sets of macromolecular mechanisms for the biosynthesis and storage of such transmitters in the different branches would be indicated. We believe that such macromolecular components are synthesized in the perikaryal region of the neuron and are subsequently transported to the terminal branches; if so, the existence of more than one set of transmitter mechanisms in a single neuron seems unlikely. Thus, the implication of Dale's law is that, during development, some process of differentiation determines which particular secretory product a given neuron will manufacture, store, and release. In biochemical terms, the difference between one neuronal type and another may not be very great. For example, studies of the axoplasmic components of lobster inhibitory and excitatory motor nerve fibers suggest that the major difference between the two may be the presence of a significantly higher activity of the enzyme glutamic decarboxylase in the inhibitory axons; that could account for the accumulation of the inhibitory transmitter GABA in these neurons (Kravitz et al., 1965). It has been suggested that the intracellular chloride-ion concentration in the vertebrate CNS might determine whether a given neuron will accumulate GABA (Roberts and Kuriyama, 1968).

Summary

In this chapter, I have tried to summarize in broad terms some of the knowledge now available concerning the neuronal mechanisms associated with neurotransmission and neurosecretion. A great deal remains to be learned of such mechanisms. In particular, we must complete the list of transmitter substances, learn more about the importance of substances that may be released along with the transmitter at the presynaptic nerve terminal, determine the role of perikaryal protein synthesis in neurotransmission, and elaborate the pharmacological armory of drugs with specific effects on particular transmitter systems.

Perhaps most importantly we might hope to begin to understand the molecular mechanisms involved in the interaction of the released transmitter with the postsynaptic receptor molecules.

59 Structure and Function of Neuroglia: Some Recent Observations

RICHARD P. BUNGE

IF WE WERE GIVEN a fleeting glance of the image of an infant cradled in his mother's arms, we might immediately presume the mother was feeding the child. Motherhood implies sustenance—it may not occur to us that the mother was, in fact, seeking to protect the child, or attempting to change a diaper. It seems correct to say that the neurobiologist, viewing the image of the nerve cell cradled in the arms of the neuroglia, has generally preferred the assumption that the glia were nourishing the neuron; this assumption has considerably influenced our thinking regarding neuroglial form and function.

Undoubtedly, this view was strengthened by the early recognition (e.g., Clayton, 1932) that some form of neuroglia was found in virtually every type of nervous system studied, both vertebrate and invertebrate (discussed in Bullock and Horridge, 1965; Bunge, 1968). It also was recognized that neuroglia could be found throughout all parts of the nervous system,* both central and peripheral, and that in many regions their numbers far exceeded the number of neurons. It is not difficult to understand how the concept of

* In this discussion, the term neuroglia is used for satellite cells and sheath cells of both the central and peripheral nervous system, and therefore will include peripheral ensheathing cells, commonly called Schwann cells. the glial cell nourishing the neuron was gradually extended in the minds of many neurobiologists until the neuron was considered dependent on glial presence.

It is now clear, however, that some situations demonstrate that certain neurons are not dependent on the presence of glia for their day-to-day existence. There are lower forms, e.g., certain coelenterates (Horridge and Mackay, 1962), in which nerve cells are not admixed with glia, and neuronal processes course among a variety of tissue types without any apparent cellular ensheathment (Figure 1A). In the development of higher nervous systems, a large part of early neuron development, including some synapse formation, occurs before substantial glial development has taken place (Bodian, this volume). It has also been observed that some genetic defects of glial development, e.g., the defective myelination of jimpy mice (Wolf and Holden, 1969), do not lead to discernible differences in neuronal maturation. Furthermore, in some regions that normally contain glial cells, neurons and their processes have survived after removal of the glial component. The cytoplasm of the massive packet glial cell surrounding the large neurons in leech ganglia can be removed mechanically; the neurons thus denuded incorporate glucose (Wolfe and Nicholls, 1967) and maintain their resting potential and ability to generate action potentials (Kuffler and Potter, 1964). A substantial number of the satellite cells and Schwann cells in mammalian sensory ganglion cultures can be destroyed by high doses of X-rays, thus denuding large areas of the neuronal soma and leaving many of the unmyelinated axons unsheathed. These neuronal elements survive for several

FIGURE 1 Schematic diagrams of various types of glial ensheathment. NF, nerve fiber; S, sheath cell. The glial component of the sheath is emphasized rather than connective tissue elements. A. In some forms nerve fibers have no sheaths at all (as in coelenterates). B. In many forms nerve fibers (or neurons) are ensheathed as a group, with a glial sheath disposed between them and their source of nutrient (as in vertebrate CNS). C. Large nerve fibers (or neurons) may be surrounded by multiple layers of glial processes (as in insects). D. In some forms, large glial cells ensheath axons singly or in groups (as in the leech). E. Multiple layers of glial processes may have some compaction between them (as in the earthworm). F. Large nerve fibers may be sur-

rounded by a single Schwann cell (as in insect peripheral nervous system [PNS]). G. Small unmyelinated nerve fibers may be enclosed in individual troughs of glial membrane (as in mammalian PNS). H. In some cases, loosely applied glial processes are irregularly spiraled around the axon (as in insect PNS). I. Very fine fibers may, in some cases, be enclosed as a group in glial membrane troughs (as in vertebrate olfactory nerve). J. Large axons may, in some instances, have a mosaic of Schwann cells applied to their surface (as in the squid). K. In vertebrate PNS (and CNS) systematic spiralization and compaction lead to the formation of myelin. (From Bunge, 1968.) weeks despite having themselves been damaged by the radiation (Masurovsky et al., 1967). It has also been observed that neurons of the autonomic nervous system can be maintained for substantial periods in culture under conditions in which few satellite cells or fibroblasts develop (Levi-Montalcini and Angeletti, 1963; Burdman, 1968). Finally, it should be noted that, in many areas of the nervous system of both invertebrates and vertebrates, neurons lie in direct contact with one another, and axons course together in bundles directly adjacent to one another without intervening sheaths (Figure 1) (for discussion, see Bunge, 1968).

The nature of "loose" ensheathment

In addition to the observations outlined above, indicating a degree of metabolic independence for the neuron, we now have a much clearer picture of the anatomical nature of the neuroglial-neuronal relationship. Some of the patterns of glial disposition that have been observed are shown schematically in Figure 1. The generalized relationship between neuronal and glial elements in many of these forms of ensheathment is depicted in Figure 2A. This Figure represents the more basic, unspecialized pattern that might be termed "loose" ensheathment. The neuronal element is harbored in an encircling glial process (or group of processes). The membrane of the glial process is brought into close apposition with the neuronal element, but generally makes no specialized contact with it. This point must be emphasized—in this simple and ubiquitous form of ensheathment there are no specialized contacts between glia and neuron, such as the regions of close membrane apposition that, it has been demonstrated, allow the direct passage of materials between cells in other systems (reviewed in Furshpan and Potter, 1968). Furthermore, the cleft between the neuron and glial cell, represented by shading in the various parts of Figure 2, is known to be relatively open and in continuity with extracellular space. In situations typical of the central nervous system of higher vertebrates, the glial cell is often interposed between blood vessels and neuronal elements, as is shown schematically in Figure 2C. Here, too, the clefts between neuron, glia, and blood vessel constitute spaces open to the movement of a variety of solutes.

Evidence for the relative looseness of this form of glial investment now is available from a variety of experiments. Observations on tissues fixed after the extracellular application of materials that are visible (or can be made visible) in electron micrographs indicate: (1) that the protein ferritin can pass into the 150-Å clefts between satellite cells and neurons in spinal ganglia of the toad (Rosenbluth and Wissig, 1964); (2) that the systems of clefts on the surface of squid nerve fibers (the mesaxon gaps, the Schwann layer channels, and the axolemma-Schwann cell spaces) allow the penetration of particles as large as those of thorium dioxide (Villegas and Villegas, 1968) (Figure 3); and (3) that ferritin molecules travel quite freely in the clefts between glia and neurons in the vertebrate central nervous system (Brightman, 1965), as do also the marker molecules horseradish peroxidase (Figure 4) (Brightman, 1968; Brightman and Reese, 1969), and saccharated iron oxide (Pappas and Purpura, 1966).

In addition to these anatomical observations, some observations on physiological aspects of neuroglial cells provide direct information regarding intercellular spaces in nervous tissue. Work on the nervous system of the leech (in which the large size of the glial cells facilitates intracellular recordings) and on the optic nerve of the mud puppy and the frog has recently been summarized (Kuffler and Nicholls, 1966; Kuffler, 1967) as follows. It has been established that the neuroglia in these species are surrounded by a high-resistance membrane and have a rather high resting potential. In the mud puppy the resting potential is about 90 millivolts, which is at the equilibrium potential for K⁺ in Ringer fluid (3 mEq per liter). These glial cells, like most cells, have a high internal K+ concentration; unlike neurons, they do not generate propagated impulses. They are frequently linked to one another, but not to neurons, by special low-resistance junctions. These aspects of glial physiology having been established, it was then possible to use the membrane of glial cells and of neurons as indicators of the external ionic environment, and to establish that, in the preparations studied, the intercellular clefts in the nervous system serve as a rapid and effective pathway for the diffusion of such ions as Na⁺ and K⁺ and for such molecules as sucrose, insulin, dextran, or choline. The movement of these substances is thought to be around the glial cells rather than through the glial cytoplasm and can be quite rapid; the time for 75 per cent exchange of Na⁺ with sucrose is about 10 to 20 seconds in the Necturus optic nerve (Kuffler et al., 1966).

Similar types of observations have also been made on peripheral nervous tissue of the squid, in which it is possible to impale axon and Schwann cell sheath cells separately for electrical recording. Here, too, the conclusion is that the narrow, intercellular clefts between Schwann cells surrounding the axon are no barrier for the diffusion of test molecules; the barrier is the axolemma itself (Figure 3) (Villegas and Villegas, 1968). Using this same preparation, these workers have also observed that axonal electrical activity is not accompanied by electrical change in the Schwann cells (Villegas et al., 1962a, 1962b, 1963).

How do we reconcile these properties of "loose" ensheathment with the known presence of firm barriers surrounding nervous tissues in many higher forms? In higher animals, there appears to be provision for a separate barrier

FIGURE 2 GC, glial cell; ECS, extracellular space. A. A generalized scheme of neuron-glial relationships is shown to emphasize the continuity (at the arrow) between the spaces around the axon and the general extracellular space. B. Manner in which ECS in certain vertebrate peripheral nerves is separated from general body fluids by a cellular sleeve, the perineurium. The close junction between overlapping perineurial cells (as at the black arrow in B) appear to form the major physical barrier to the general body environment. As shown in C, the extracellular spaces be-

tween neurons and glia in mammalian CNS, although small, are believed to be relatively open. The barrier for the passage of protein out of or into CNS blood vessels is known to be at the endothelium of the blood vessels (black arrow). The narrow extracellular spaces of the brain are considered in general continuity with both ventricular and extraventricular cerebrospinal fluid (labeled ECS). A small nonensheathing oligodendrocyte is shown in C. (See text for details.)

FIGURE 3 Electron micrograph of squid nerve fibers, showing marker molecules (thorium dioxide) that have been applied outside the nerve penetrating into the spaces between Schwann cell (SC) and axons (the roughly circular profiles within the Schwann sheath). \times 87,000. (From Villegas and Villegas, 1968.)

system apart from the glial ensheathment under discussion. This barrier system involves the anatomical arrangement and function of the blood vessel endothelium on one hand, and the provision of special encasing membranes on the other. In the distal peripheral nerve of higher vertebrates, as shown schematically in Figure 2B, an encasing sleeve of cells, termed the perineurium, surrounds individual nerve fascicles (see review by Shantha and Bourne, 1968). The inner layer of this encasing sleeve is complete, like a squamous epithelium, and the cells comprising the layer are joined to one another by regions of close membrane apposition. These regions form the barrier that prevents entry of externally applied horseradish peroxidase and lanthanum hydroxide (Reese and Olsson, 1970) and ferritin (Waggener et al., 1965). Epineurial blood vessels, which course within the distal nerve outside the perineurium, appear to be permeable to albumin; when these vessels course internal

FIGURE 4 Electron micrograph illustrating the presence of a protein marker, horseradish peroxidase, in the extracellular clefts of the mouse CNS. The marker was placed in the ventricle and entered the brain spaces between ependymal cells; it has penetrated between the numerous cell processes and between astrocyte endfeet adjacent to a blood vessel (upper right). \times 34,000. (Courtesy of Dr. M. Brightman; see Brightman and Reese, 1969.)

to the perineurium, into the spaces and tissues immediately surrounding the nerve fiber itself, they are not normally permeable to albumin (Olsson, 1968) or to horseradish peroxidase or lanthanum hydroxide (Reese and Olsson, 1969). If vascular permeability of vessels entering this space is abnormal, proteins may leak into the region inside the perineurium and perfuse the tissues of the endoneurium. There is some evidence that proteins in this space can gain access to the clefts between Schwann cells and axon (Kaye et al., 1963; Waggener et al., 1965). Thus, the direct barrier for large molecules in these regions of peripheral nerve appears to be not the glial cell but a "tight" vascular system and a special encasing membrane, the perineurium.

In the central nervous system, the arrangement of barriers is much too complex to be discussed in detail here, but there are certain parallels. In Figure 2C, a portion of the central nervous system is shown schematically to emphasize the point that the extracellular fluids in the clefts between cells are apparently part of a compartment that is continuous with the cerebrospinal fluid and is isolated from the blood plasma. The anatomical evidence for this diagram is substantial and has recently been reviewed (Brightman, 1968; Brightman and Reese, 1969; among others). Available evidence indicates that large molecules within the blood stream do not normally enter the brain parenchyma because they are blocked by close junctions between the endothelial cells of blood vessels (Reese and Karnovsky, 1967). Large molecules introduced into the cerebrospinal fluid (CSF) are not restrained by ependyma or pia, and enter the clefts of the nervous system readily; in a similar way, large molecules within the clefts of the CNS parenchyma move readily into the CSF compartment (discussed in Brightman and Reese, 1969). Work on the ionic environment of neurons and glial cells in the brain of an amphibian have indicated that cells within the optic nerve are surrounded by an ionic environment that corresponds more closely to that of the CSF than to that of blood plasma (Cohen et al., 1968). The intercellular clefts of this CNS preparation were found to be open, and ions diffused freely into them from the CSF. This compartment, which includes the CSF and the brain spaces, has special homeostatic mechanisms keeping the ion concentrations around neurons and glia within a narrow range and relatively independent of large changes in the blood plasma (see also Katzman et al., 1968).

It should be emphasized that this cursory discussion of barriers and spaces applies to higher vertebrates; such discrete anatomical barriers may be absent from certain invertebrate nervous systems (e.g., Eldefrawi et al., 1968). The generalization seems justified that where firm barriers exist between nervous tissue and general body fluids they are generally provided by special, nonglial membranes, rather than by glia. The clefts between neuron and glia are open; the glial cell does not comprise the extracellular space for the neuron. (The site of the blood-brain barrier for protein in the shark brain may be an exception to this generalization, according to Brightman et al., 1970.)

Specializations of glial ensheathment: the myelin sheath

In contrast to the relative "openness" of the clefts between glia and neurons discussed above, in a variety of instances a compaction of glial cell processes around the neuron clearly results in a direct regulation of the environment in the vicinity of the neuron and thus alters its functional properties. One such instance is the myelin sheath. Normally, the ionic currents that are generated during the actionpotential flow in the spaces between sheath cell and axon, as well as in the clefts between sheath-cell processes (refer to Figures 1 and 2). If the lips of the ensheathing process were brought together and "sealed" against one another, as in a close junction (Figure 5), the ionic currents generated by axolemmal conduction would be constrained; this form of sheath would be expected to have a high resistance to radial current flow. If the capacitance of the ensheathing membrane was low, so that little current would be used to "charge up" the sheath, the ionic currents would tend to move along the core of the axon until a site of lower resistance for radial current flow was encountered. These are, of course, the properties of the myelin sheath. Myelin ensheathment differs from that discussed previously in that the ensheathing membranes are systematically compacted together in a form of close junction that is known, in other systems, to provide barriers to extracellular movement of many forms of materials, including ions (e.g., Farquhar and Palade, 1965). Periodically, this compacted form of ensheathment must be interrupted and the constraints on the periaxonal space lifted to allow regeneration of the action potential; these interruptions are the nodes of Ranvier. Here the axolemma is exposed to the usual (or an increased) amount of extracellular space and appears specialized (reviewed by Peters, 1968). The periaxonal space under the myelin would be open to the general extracellular space in the nodal area, but special forms of contacts are also provided in this region (Figure 5). Whether these special nodal glial-axon contacts are needed to aid in the "sealing" of the internodes against ionic currents or whether they provide necessary structural support is not known. Details of peripheral and central myelin and nodal structure have been recently reviewed (Peters, 1968; Elfvin, 1968).

Although it is known that the myelin sheath does provide a high resistance and a low capacitance (Hodgkin, 1964), the exact "tightness" of the seal it provides for the axon is not known. Lanthanum has been observed to penetrate the space between the myelin sheath and the axon of the CNS (Brightman and Reese, 1969), and recently Hirano et al. (1970) have observed that externally applied lanthanum hydroxide marks the region between the special contacts made by the glial cell and axon at the region adjacent to the node. It has also been recently observed that myelin lamellae may present a potential cleft in the interperiod line (Napolitano and Scallen, 1969; Revel and Hamilton, 1969). The myelin "seal" may be only relative, but it is sufficient to provide the control of current flow necessary for saltatory conduction.

Metabolic properties of myelin

The prevailing view for much of the past decade has been that the components of myelin were relatively stable and, hence, that myelin was relatively inert. Myelin was some-

FIGURE 5 A. A nodal region from vertebrate PNS (above) and CNS (below). In the PNS, the Schwann cell provides an internal collar (Si) and an outer collar (So) of cytoplasm in relation to the compact myelin. Terminating loops of the compact myelin come into close apposition to the axolemma in regions near the node in both PNS and CNS; in PNS, Schwann cell processes are coated externally by basement membrane (b.m.) and are loosely interdigitated at the node. D illustrates the confinement of the periaxonal space (marked *) by the compaction of the spiraled membrane of the myelin sheath. In part B a normal intercellular con-

figuration is shown; in part C a region of close membrane apposition. When cells are in contact, as in B, materials move quite freely from c to d, but not from a to b. In cells closely apposed, as in C, the movement of small molecules from a to b often is facilitated, and the movement of material from c to d restrained. If the close contacts between myelin terminal loops and axolemma and between compacted myelin lamellae function in this manner, the periaxonal space is relatively isolated from the general extracellular space. For details, see text. (From Bunge, 1968.)

times viewed simply as a physical insulator, without reference to its derivation from, and dependence on, a living cell.

During the past few years this picture has been changing rapidly. The mechanism by which the peripheral myelin sheath is derived from the spiral disposition of Schwanncell membrane has been clarified, and a similar mechanism has been observed during the formation of central myelin from the oligodendrocyte (see review by Bunge, 1968). It has been directly observed that in the CNS more than one segment of myelin may derive from one glial cell; it has recently been estimated that as many as 30 segments may be related to a single oligodendrocyte in the optic nerve of the rodent (Peters and Proskauer, 1969). Our current concept of the anatomy of the central myelin sheath and the myelin-related oligodendrocyte (reviewed by Hirano and Dembitzer, 1967; Bunge, 1968; Peters, 1968) is shown schematically in the three parts of Figure 6. If the myelin segments believed to be related to one oligodendrocyte are unrolled from their usual spiral disposition around the axon, the cell would appear as shown in Figure 6C. The cytoplasm related to central myelin is thus seen to be in tenuous (but probably permanent) connection with the cell body of an oligodendrocyte (Figure 7). At first glance, the configuration of this glial cell seems incredible. When depicted as in Figure 6, however, the cell reveals remarkable similarities to certain neurons that also have long, slender extensions (as axons and dendrites) from the cell body. Is it surprising that a single oligodendrocyte supports several dozen segments of myelin if a single neuron can support a similar number of distally located neuromuscular junctions? It is also interesting to note that the chief cellular organelle present in the narrow extension of oligodendrocyte cytoplasm bordering the compacted regions of myelin is the microtubule (inset, Figure 7). These microtubules (so much

FIGURE 6 Drawings to show the CNS myelin-related cell (the oligodendrocyte) and its postulated relation to segments of myelin. A. The configuration of the cell body as reconstructed from serial sections. (From Stensaas and Stensaas, 1968.) B. The oligodendrocyte in continuity with

many segments of myelin in the usual spiraled and compacted configuration. C. The myelin segments in an unrolled configuration. The cytoplasmic extensions of the oligodendrocyte related to myelin have certain similarities to the axonal extensions of neurons.

FIGURE 7 Electron micrographs showing CNS myelin and the myelin-related oligodendrocyte. Large E. M. shows the extended process of an oligodendrocyte in kitten spinal cord in tenuous connection (at the arrow) with the membrane of the myelin sheath forming around the axon marked a. The process contains mitochondria, ribosomes, numerous elements of the endoplasmic reticulum, and microtubules. Other myelin sheaths are in various stages of formation.

The inset shows a small myelinated axon and demonstrates particularly well the myelin-related cytoplasm situated both internal (C_i) and external (C_e) to the compacted myelin layers. This cytoplasm contains profiles of micro-tubules cut in cross section. \times 28,000; inset, \times 166,000. (Figure courtesy of M. B. Bunge; inset, from Hirano and Dembitzer, 1967.)

studied in relation to axon transport systems) may, in the case of the myelin-related cell, function in facilitating the passage of materials from the cell body into the remote regions of the myelin internode. Indeed, agents such as vinblastine, which affect the organization of microtubules in neurons and axons, similarly affect microtubules in the myelin-related cytoplasm of oligodendrocytes (Schochet and Lampert, 1969). We thus have the picture of the central myelin-related cell with its major cellular machinery concentrated in a perikaryal area but devoted to maintenance of an extensive membrane system some distance away. The same pattern is seen in the neuron—a cell body devoted in large part to the maintenance of its distant extensions and synaptic endings.

Along with this advance in anatomical thinking regarding myelin, there has been increasing evidence that certain chemical components of myelin are turning over at considerably faster rates than would have been expected from early work (discussed in Hendelman and Bunge, 1969). Recent experiments (Horrocks, 1969) indicate that the ethanolamine phosphoglycerides of the myelin fraction of central nervous tissue have an apparent half-life of less than three days (see also Ansell and Spanner, 1967). A half-life of two and a half days has been reported for the sulfatides of the myelin fraction from mammalian brain (Davison and Gregson, 1966). Although these components may be only a portion of the total myelin lipids, the results do point to the necessity for a supporting cell as an active site of the synthetic activity necessary for the maintenance of an intact myelin sheath. In addition, there is the intriguing observation that diphtheria toxin, the potent and specific demyelinating agent (see McDonald and Sears, 1969), acts in certain tissues as a powerful inhibitor of protein synthesis (discussed by Gill et al., 1969). These observations point to specific roles for the myelin-related cell in maintenance as well as in myelin formation, and offer new hope of understanding whether specific demyelinating diseases may result from metabolic deficiencies rather than from the more commonly considered external attack.

Additional data that are changing our concept of the myelin sheath as a static structure are the observations that myelin may undergo a most dramatic splitting and swelling when poisoned with triethyltin (e.g., Hirano et al., 1968) and the recent report (Lampert and Schochet, 1968) that this reaction is similar to that observed in edema in the cerebellar white matter of ducklings treated with isonicotinic acid hydrazide (INH). It seems likely that, when the pharmacology of triethyltin action is better understood and a possible relation to INH action is explored, we may gain new insight into the agencies stabilizing the myelin sheath.

Recently it has been suggested that the myelin sheath, in addition to its effects on impulse conduction, may function to nourish the axon directly (Fleischhauer and Wartenberg, 1967; Singer, 1968). This suggestion derives in part from

the observation that radioactivity from labeled amino acids (and uridine) injected systemically can be demonstrated in the myelin sheath (and myelin-related Schwann cell) earlier than it is observed in the axon; this same pattern can be seen if the axon has been severed from its parent cell. There can be many explanations of this observation, taking into consideration the possibility of metabolism directly related to myelin maintenance, as well as the possibility of synthetic mechanisms in the axon itself (Edström and Sjöstrand, 1969). Because it is known that axons can survive for extensive periods (McDonald, 1967) without myelin, and because there is evidence for incorporation of materials directly into myelin (and its related cell) as well as into the axon (Edström and Sjöstrand, 1969), a clear demonstration that materials move between myelin and axon seems most difficult.

Forms of ensheathment related to myelin

It should be pointed out that certain invertebrates apparently achieve a form of saltatory conduction of the nerve impulse without the systematic spiralization and compaction of glial processes that characterize vertebrate myelin. The prawn has nerve fibers surrounded by partially compacted glial processes that are disposed concentrically around the axon (Heuser and Doggenweiler, 1966) and interrupted periodically by nodes. Without providing systematic compaction of the glial processes, this system allows conduction velocities of up to 20 meters per second. In a giant nerve fiber in the ventral nerve cord of certain shrimps, a highly compacted sheath apparently constrains ionic currents to an extracellular space between the axon and the sheath (Kusano, 1966). This sheath extends without interruption from one ganglion to the next, a distance of about 5 mm, and allows conduction velocities of up to 210 meters per second. Recently Hess et al. (1969) have established a relationship between the appearance of the myelin that ensheaths the synaptic apparatus of the avian ciliary ganglion and the appearance and persistence of electrical coupling in this region.

Functional aspects of loose ensheathment

The "tight" type of glial sheath discussed above dramatically influences the properties of the periaxonal region, and thus alters the functional properties of the neuron. Do the "loose" forms of ensheathment discussed earlier influence the physiological properties of the underlying neuronal membrane? There is evidence that this type of glial sheath functions in the regulation of the neuronal environment; this is the theme of the ensuing discussion.

We know, first, that the very narrowness of the intercellular gap between neuron and glia can influence axolemmal responses. Experiments on the squid giant axon (Frankenhaeuser and Hodgkin, 1956) support the view that the increment of K+ released during the passage of an action potential is concentrated briefly in the narrow clefts between the axon and the adjacent glial sheath (see Figure 1). This momentary K⁺ accumulation accounts for the negative after-potential recorded across the axonal membrane. Orkand et al. (1966) have demonstrated that nerve impulses in the optic nerve of the mud puppy and frog consistently lead to a decrease in the resting potential of glial cells. They further demonstrated that this effect was not mediated electrically, but was caused by K+ release from unmyelinated nerve fibers during activity. In fact, prolonged maximum stimulation at 10 per second or more could lead to a complete block of conduction, the glial cells being depolarized as much as 48 millivolts in some experiments. This depolarization could definitely be attributed to K⁺ accumulation in the extracellular clefts, and could also be demonstrated after natural stimulation of the retina. Nicholls and Kuffler (1964) showed that the glial-cell resting potentials, in another preparation, are much more sensitive to depolarization by increasing K⁺ concentrations than are neuronal resting potentials. In discussing their observations, these authors suggest that glia surrounding especially active axons might serve to distribute the K+ released from these areas to adjacent regions via an intracellular pathway (continuous from glia to glia via low-resistance junctions). This movement of current would then contribute to surface potentials recorded with extracellular electrodes. The contribution of the electrical properties of glia to slow-potential changes in nervous tissue has been frequently discussed (Kuffler and Nicholls, 1966; MacKay, 1969; see also Karahashi and Goldring, 1966; Grossman and Hampton, 1968).

Kuffler and Nicholls (1966) suggested that this signal, mediated by K⁺ and traveling from neurons to glia, could serve as a trigger for release of metabolites from glial cells for use by neurons. The large, ensheathing glia under discussion commonly contain large amounts of glycogen, especially in invertebrates (Wigglesworth, 1960). It is tempting to suggest that these reserves can be made available to the neuron, but direct evidence for such an exchange is lacking (see Wolfe and Nicholls, 1967).

There is, in fact, no direct evidence for the transfer of material from glia to neurons. The search for such an exchange has generally focused on metabolites useful to the neuron in energy production or anabolic processes. Recently, however, there has been considerable discussion of how the glia may assist the neuron in catabolic and protective processes. Palay (1966) suggested that the disposition of a glial mantle around synaptic groupings in certain regions of the CNS may protect these regions from being influenced by adjacent synaptic activities, presumably by somehow limiting the spread of neurotransmitters (Figure 8). Salpeter (1969) has demonstrated that a portion of the acetylcholinesterase activity at the neuromuscular junction reresides in the glial cap overlying the nerve terminal. Observations made by Smith and Treherne (1965) on cockroach ganglia may be related. Acetylcholine has been considered as a probable neurotransmitter in the insect nervous system, but, paradoxically, large amounts of topically applied acetylcholine have little effect on electrical activity in the cockroach ganglion. Smith and Treherne (1965) found that ¹⁴C-labeled acetylcholine not only penetrates rapidly into the CNS of the insect, encountering no apparent diffusion barrier, but also is rapidly metabolized on entry. In the presence of the anticholinesterase, eserine, the penetration of acetylcholine into the nervous system was not impaired, but its hydrolysis was inhibited. They concluded that in explaining the relative insensitivity of the insect's central nervous system to acetylcholine it was not necessary to postulate an exclusion of this material from CNS tissue; the phenomenon could be accounted for by the activity of the cholinesterase system in the ganglion. Their histochemical studies indicated that cholinesterase activity was particularly well marked in the glial sheath surrounding axons and neurons.

In a situation somewhat parallel to the one above, Hoskin et al. (1966) applied a potent cholinesterase inhibitor, the insecticide di-isopropylphosphorofluoridate (DPF) to preparations of squid giant axons. When ¹⁴C-labeled DPF is applied externally, radioactivity rapidly accumulates in the interior of the axon. The compound appearing in the axon is not DPF, however, but its inactive hydrolysis product, di-isopropyl phosphoric acid. Both the axoplasm and, more importantly (to use their words), the axonal envelope, including the Schwann cell and associated connective tissue, contain sufficient DPF-hydrolyzing enzyme to account for the relatively high concentration of DPF required to affect electrical activity in this preparation. Another observation that supports the general concept that glia regulate the content of extracellular fluids is that glial cells are active in the uptake of proteins present in abnormally high amounts in the intercellular clefts (Blakemore, 1969; Brightman, 1968).

These examples provide the background for what has been termed the gantlet concept (Bunge, 1968) of glial function. The neuron exposes extremely sensitive membranes to the general extracellular environment of the nervous system. Yet it cannot seal off the neuronal plasma membrane to protect it against straying neurotransmitters, neurohumors, toxins, and the like. By forcing substances of this type to run the narrow gantlet of the ensheathing extracellular space in which enzymatic breakdown or uptake can take place, a mechanism may be provided for protection of the axolemma without providing an actual seal. Recent observations (Orkand and Kravitz, in press) on the uptake of gamma aminobutyric acid (GABA) by lobster peripheral

FIGURE 8 Diagrammatic representation of the relationship between a neuron and astrocytic processes. The surface of the neuronal soma is covered with thin cytoplasmic extensions of astrocytes. These also ensheath synaptic regions.

nervous tissue have indicated that this agent (a known transmitter at lobster neuromuscular junctions), when applied externally, is concentrated in the glial and connective tissue sheath cells of the nerve, rather than in the neuronal element (Figure 9). If this uptake is a mechanism for terminating the action of GABA released at synaptic clefts, the system provides a specific example of the contribution of nonneuronal cells to the control of the immediate milieu of the neuron.

A related view regarding the functioning of the narrow extracellular clefts of the brain is discussed in detail elsewhere in this volume. Focusing on the properties of the mucoproteins and mucopolysaccharides that are known to coat cell membranes, including neuronal and glial cell membranes (discussed in Schmitt and Samson, 1969), various workers have suggested that important properties of the extracellular space could be expected to vary as the physical

In the more distal regions of the dendrite, groups of synaptic terminals are often surrounded by a common astrocytic mantle. (From Wolff, 1968.)

state of the components varied (e.g., Adey et al., 1969). Factors such as hydration and divalent-cation binding by these extracellular components could influence the dimensions and the conductance properties of the intercellular spaces and could significantly alter neuronal function, possibly for extended periods. This view comes into conflict with the discussion above only if these large-molecularweight intercellular materials are considered to be a complete "filler" material for the regions between nervous system cells. They cannot effectively fill these regions, as the nonselective extracellular movement of materials as large as protein has been clearly demonstrated (as discussed above). The matter is further complicated by observations which suggest that the amount of space between cells in nervous tissue may change in response to alterations in the permeability of adjacent cell membranes (e.g., Van Harreveld et al., 1965). We now know there are extracellular spaces in

FIGURE 9 Electron-microscope autoradiogram illustrating the sites of GABA binding in lobster peripheral nerve. Labeled GABA was applied externally and, after uptake, was bound to the tissue with a fixative containing glutaraldehyde. The autoradiogram shows label over glial and

nervous tissue, but we need to know much more about their exact dimensions and their specific properties.

Other glial-neuronal interactions

The discussion above has concerned primarily those glial cells that function as ensheathing cells in the central and connective-tissue components surrounding the axon (a). The ensheathing cells contain glycogen-like granules (g) and are interspersed with connective tissue fibers (ct). \times 18,000. (From Orkand and Kravitz, in press.)

peripheral nervous systems. There are, especially in higher nervous systems, small cells (the perineuronal oligodendrocytes) that are often disposed as neuron satellites (Figure 2c). Functional aspects of these cells have been discussed in detail by Hydén (1967), with special emphasis on metabolic exchange between neurons and glia in a variety of physiological states. These aspects cannot be considered in detail here, but it should be noted that the type of preparation used in the experiments has evoked considerable recent discussion. A clean separation of glial material from neurons has been attempted, but the purity of the glial preparation has been questioned by several investigators (Kuffler and Nicholls, 1966; Sotelo and Palay, 1968). Similar reservations apply to the recent observations by Hertz (1966) on alterations in "glial" respiration induced by altered Na⁺ and K⁺ levels; we have no information regarding the cellular homogeneity of the glial material. Some of the problems of glial isolation from mature nervous tissue have been discussed recently by Cremer et al. (1968).

What do glial cells do?

The general theme I have presented above is that glia assist in regulating the neuronal environment. When this is done in a dramatic way, such as by the deposition of myelin, the mechanism of glial function can be discerned relatively clearly. When more subtle regulation is involved, the exact function of the glia becomes less clear. The brisk glial responses that occur in the region of the neuronal cell body after an injury to a distant portion of the axon (e.g., Friede and Johnstone, 1967; Blinzinger and Kreutzberg, 1968) suggest that there is, in fact, considerable metabolic "crosstalk" between neurons and glial cells. The earlier allusion to the mother-child relationship again seems appropriate. There is a multitude of overt and subtle interchanges between mother and child; after centuries of observation new aspects of this relationship are still being defined. It is perhaps not surprising that so few precise functions of neuroglia are known at present.

Summary

Several recent observations suggest that neurons may not depend so directly on neuroglia as has generally been believed. Also, recent evidence indicates that the general form of neuroglial investment (such as that provided by astrocytes and by Schwann cells related to unmyelinated fibers) is a "loose" ensheathment, permitting considerable movement of solutes in the extracellular spaces. Myelin is presented as as an exception to this generalization, representing a systematic compaction of glial processes which are arranged to influence directly the ionic current movement in the vicinity of the axon. The anatomical disposition of the myelinrelated cell in the CNS (the oligodendrocyte) is considered, and the mechanisms by which the metabolic demands of myelin may be met are discussed.

Observations indicating that neuroglia generally have a comparatively high resting-membrane potential, and a high internal K^+ level, are reviewed. The K^+ -mediated glial depolarization that follows neuronal activity is discussed.

Several other instances are cited in which glia appear to contribute to the control of the immediate environment of the neuron. The general picture presented is that of neuroglia functioning primarily as regulating agents rather than as indispensable partners of the neuron.

Acknowledgments

Work in the author's laboratory is supported by Grant NB-04235 from the National Institutes of Health, and Grant 428 from the National Multiple Sclerosis Society. I am grateful to Drs. G. Villegas, J. Wolff, A. Hirano, L. Stensaas, and M. Brightman for providing illustrative material from published work, and particularly thankful to Drs. Orkand and Kravitz for providing details of their work and the electron-microscope autoradiogram in Figure 9, prior to their publication. Mr. Robert Demarest provided the drawings in Figures 1, 2, 5, 6B, and 6C.

70 A Comparison of Invertebrate and Vertebrate Central Neurons

MELVIN J. COHEN

THE PAST 30 YEARS of intensive study on conductile processes within single units of the nervous system have emphasized that neurons throughout the animal kingdom have many features in common (Bullock and Horridge, 1965). Information from the squid axon, crustacean nerve fibers, or neuromuscular junctions in the crab and the frog have been used for formulating models of nerve conduction and transmission that appear to apply to neurons in general, including the central nervous system (CNS) of man. Similar generalities have been arrived at in the sensory realm through a comparative approach; the eye of *Limulus* (Hartline et al., 1952) and the muscle receptor organ of a crustacean (Kuffler, 1954) provide classic examples of studies in sensory function that are of broad significance.

It may, however, be imprudent to assume that such generality of function also applies to questions involving interaction between members of a population of central neurons. Such questions deal with the geometry of connections underlying a particular act of behavior, how these connectivity patterns develop, and how they are stabilized or modified during the lifetime of the organism. Here we must look at the entire neuron and expand our consideration beyond those facets concerned with the propagation and transmission of electrochemical signals. In this context, the relationship between the bioelectric activity of the neuron and the control of macromolecular synthesis in the nerve cell body may be of particular importance. The central neurons of invertebrates differ from those of vertebrates in the degree to which the specialized synaptic and conducting components of the neuron are separated from the genetic apparatus of the soma. This isolation of the central nerve-cell body from the synaptic field in invertebrates may be related to the predominance of genetically determined stereotyped behavior found within the invertebrates in contrast to the marked labile behavioral potential of the vertebrates. To these differences between the central neurons of vertebrates and invertebrates, and their possible relationship to behavior, this essay is addressed.

Morphological comparisons between invertebrate and vertebrate central nervous systems

Figure 1 is a photograph of a living central ganglion in the larva of an invertebrate, the phantom midge (Chaoborus). Notice that the soma of the two large neurons are pushed to the periphery of the ganglion. The central portion of the ganglion is essentially devoid of cell bodies and consists of neurites, which form a dense neuropil. This is the area in which transmission and propagation of signals take place. The separation of neuronal somata from neuropil is further demonstrated in Figure 2, which is a transverse section through a thoracic ganglion of the cockroach Periplaneta americana (Cohen and Jacklet, 1967). It is stained with the basic dye pyronine-malachite green, to show the distribution of nerve-cell bodies. The nerve-cell bodies are confined to a peripheral rind about the ganglion; the central core, containing neuronal processes (neurites), is seen to be devoid of cell bodies. Compare this peripheral distribution of neuronal somata with that seen in sections through the vertebrate central nervous system, as illustrated in the chapter by Nauta and Karten in this volume. The cell bodies in the vertebrate material are seen to be distributed throughout the entire depth of the tissue, in marked contrast to their peripheral location in the invertebrate ganglia.

Figure 3 shows a neuron from the ganglion of the larva of the dragonfly *Aeschna* (Zawarzin, 1924). The soma is smooth and gives rise to only one process, which runs centrally into the neuropil. There, the single neurite may branch in complex patterns, and it is these fine processes that form the postsynaptic complex that is analogous to the dendritic tree of the vertebrate neuron. The cell body itself is devoid of processes, and the central neuron has no known synapses on its surface. It is characteristic that the central neuronal soma in invertebrates is physically removed from the area of synaptic transmission and impulse initiation.

A summary of types of neurons in vertebrates is shown in Figure 4 (Bodian, 1967). A primary feature of the interneurons and effector neurons in the vertebrate central nervous system is the complex branching of the dendritic tree from the soma. The dendritic tree is involved in the transmission of electrochemical signals from one unit to another.

MELVIN J. COHEN Department of Biology, Yale University, New Haven, Connecticut

FIGURE 1 A ventral nerve cord ganglion of the phantom midge *Chaoborus crystallinus* seen with Nomarsky interference optics through the transparent cuticle of the living intact animal. The nucleus (n) and nucleolus (nl) are clearly

visible in each of two large nerve cell bodies at the posterior edge of the ganglion. Small cells (s) are seen around the perimeter of the large cells. (From Cohen, 1969.)

FIGURE 2 Transverse section through the anterior region of the metathoracic ganglion of the cockroach *Periplaneta americana*. The stain is pyronine-malachite green to show

primarily the nerve cell bodies. Note the peripheral distribution of nerve cell bodies and their absence in the central neuropil region. (From Cohen and Jacklet, 1967.)

FIGURE 3 Motor neuron from the thoracic ganglion of the dragonfly larva Aeschna drawn from a methylene blue preparation. The thin link segment (Zf) joins the cell body (z) to

an expanded area from which the dendrites (Mf) and the axon (Nf) originate. (From Zawarzin, 1924.)

FIGURE 4 A summary of major neuron types found in the mammalian central nervous system. Note the extensive dendritic expansions of the central somata as contrasted to

the smooth soma of the typical invertebrate central neuron seen in Figure 3. (From Bodian, 1967.)

Thus the soma, together with its genetic apparatus for the control of macromolecular synthesis, is thrust directly into the path of ionic and chemical transmitter fluxes related to synaptic transmission and impulse initiation. This is in contrast to the monopolar neuron, typical of the invertebrate CNS, the soma of which is often far removed from the sites of synaptic transmission and impulse initiation. Indeed, the greatest resemblance of neuron types in the two groups is between the invertebrate central neuron and the vertebrate dorsal-root ganglion cell, pictured in Figure 4. This vertebrate cell type also has its soma removed from the path of impulse propagation. The role this sensory cell plays in providing reliable information about the environment is also most effectively fulfilled by minimizing the variability of its response to a given stimulus throughout the lifetime of the organism.

The identification of individual central neurons

CELL BODY MAPS An examination of Figure 2 gives the impression of relatively few nerve-cell bodies present throughout the metathoracic ganglion of the cockroach. Many of the cells range from 40μ to 80μ in diameter. Cell counts provide estimates of approximately 3500 nerve-cell bodies for the entire ganglion (Cohen and Jacklet, 1967). Pringle (1939) indicated that each leg muscle in the cockroach (*Periplaneta*) receives a small number of motor axons, and it has been determined electrophysiologically that no leg muscle receives more than five axons (Pearson and Bergman, 1969). Such a relatively simple system appears open to an identification of the actual neural elements involved in a particular behavioral act. This led us to attempt to map individual motor nerve-cell bodies that drive particular muscles in the metathoracic leg of the cockroach.

If the axon of a cockroach motor neuron is cut in the leg nerve, a dense ring of RNA appears within 12 hours after injury in the cytoplasm surrounding the nuclear membrane, and reaches a peak density at about 48 hours, as seen in Figure 5 (Cohen and Jacklet, 1965; Cohen, 1967b). The perinuclear RNA ring disappears in approximately one week, and at this time the injured neuron may begin to regenerate its axon (Bodenstein, 1957; Guthrie, 1962). The cytoplasmic response to axon injury bears some resemblance to that seen in vertebrate neurons and classified under the general term of chromatolysis (Nissl, 1892; Bodian, 1947). We have used the perinuclear RNA ring evoked by injury as an anatomical marker to construct cell maps of the cockroach metathoracic ganglion. These maps indicate which motor nerve-cell bodies send their axons out a particular peripheral nerve trunk (Cohen and Jacklet, 1967). As seen in Figure 6 the distribution of motor nerve-cell bodies is bilaterally symmetrical within the ganglion. Comparison of cell maps constructed from several animals indicates that the

location of individual cell bodies within the ganglion is similar from one animal to the next. Such neuronal maps, illustrating the constancy of cell number and location, have been constructed for a number of invertebrates, including the leech (Nicholls and Baylor, 1968) and the mollusks Aplysia (Hughes and Tauc, 1962; Kandel et al., 1967) and Tritonia (Dorsett, 1967; Willows, 1967). Among the arthropods, the work of Otsuka et al. (1967) on the lobster locates individual central neurons and correlates the presence of presumed specific chemical transmitters with the determined function of these cells. The studies of Kennedy et al. (1969) have provided detailed maps correlating cell-body localization with a precise analysis of motor function in the crayfish central nervous system. These studies all point to a remarkable consistency of cell location and function within central ganglia in a wide variety of invertebrates.

THE DISTRIBUTION OF NEURITES WITHIN THE NEUROPIL The precise structural and functional identification of nerve cells within a variety of central ganglia in invertebrates has been extended to the neurites of these cells by the use of a dye-injection technique developed by Stretton and Kravitz (1968). The fluorescent dye Procion Yellow can be injected into the soma or large branches of a central neuron and will diffuse throughout the cell, including the fine neurites within the neuropil. The dye becomes fixed to the interior of the neuron and, when examined with fluorescence microscopy either in whole mount or in section, the detailed configuration of the soma and its branches can be determined. By stimulating and recording from various parts of the neuron with a dye-filled electrode, one can resolve the precise function of the cell or of its component parts. The dye is then injected into the experimental cell and the configuration of the fine branches within the neuropil determined. Figure 7 (page 804) is a $10-\mu$ section from the metathoracic ganglion of the cockroach (Periplaneta), showing the soma and processes within the neuropil of a motor neuron to the extensor tibia muscle of the leg. We penetrated the neuron with a dye-filled electrode through which a current was passed to stimulate the neuron and observed which leg muscle was activated (Rowe et al., 1969). Figure 8 (page 805) shows a cockroach motor neuron reconstructed from 10-µ serial sections. Our work on insect central neurons indicates a consistent species-specific branching pattern of processes within the neuropil for the same identified neuron. There also appear to be differences between major functional groups, i.e., between neurons innervating the extensor of the tibia and those innervating the flexor.

This type of investigation has been carried out in considerable detail on the well-studied motor neurons and interneurons of the crayfish abdominal cord (Kennedy et al., 1969; Selverston and Kennedy, 1969). The particular

FIGURE 5 Top: Cockroach central neurons the axons of which were cut two days before fixation and stained with pyronine-malachite green to show RNA. Note the dense perinuclear RNA ring in these cells. Bottom: Bilaterally

matched control cells with intact axons from the opposite side of the same ganglion. Note the relative absence of the perinuclear RNA ring in these cells. (From Cohen, 1967b.)

power of this work has been the detailed correlation of electrophysiological properties of the neuron with the microstructure of its dendritic tree. These investigators again find a high degree of consistency from one animal to the next in the dendritic branching pattern of a particular identified neuron. In the reconstructed crayfish interneuron seen in Figure 9 (page 806), note again that the soma is far removed from the densely branched dendritic tree within the neuropil.

The differentiation of neurites

The geographic isolation of the soma of the central neuron in arthropods from the dendritic branches within the neuropil appears to reflect a functional, as well as a structural, isolation of the soma from the electrogenic region of the neuron. The single process arising from the soma may run for several hundred microns into the neuropil before it expands in diameter and gives rise to dendritic branches

FIGURE 6 A three-dimensional rendering showing the distribution of some identified motor nerve cell bodies in the cockroach metathoracic ganglion. Members of a bilaterally matched pair of cells are given the same number on each

side of the ganglion. Ant. conn., anterior connectives; Post. conn., posterior connectives; N2 to N6, peripheral nerve trunks. Length of ganglion is approximately 1 mm. (Modified from Cohen and Jacklet, 1967.)

(see Figure 9). I propose that the length of neurite between the soma and the expanded region yielding the dendritic tree be called the *link segment*. Sandeman (1969b) has termed the expanded process from which the fine dendrites emanate the *integrating segment*. The smooth, often tenuous, link segment therefore joins the neuronal soma to the highly branched integrating segment within the neuropil.

THE LINK SEGMENT The relationship between the thin link segment arising immediately from the soma and the expanded integrating segment is shown in Figure 10 (page 807) for cell 3 in the metathoracic ganglion of *Periplaneta* (see Figure 6 cell map). In the cockroach, the length and diameter of the link segment vary from one cell type to the next. Kennedy et al. (1969) have pointed out that there is also variation in this part of the crayfish neuron; the interneuron has a longer and thinner link segment separating the soma from the rest of the cell as compared with the motor neuron. The longer and thinner the link segment, the more attenuated are the passively conducted electrical potentials reaching the soma. In some crayfish cells, the soma is completely isolated electrically from the rest of the neuron (Selverston and Kennedy, 1969). For the most part, in cells of insect thoracic ganglia the isolation of the soma from electrical events occurring within the neuropil is virtually complete. This has held true, in our laboratory and elsewhere, for the cockroach (Rowe, 1969) and for the cricket (Bentley, personal communication).

No definitive intracellular work has been done on the electrical properties of the link segment. Judged from the degree to which the soma reflects electrical activity taking place in the synapses of the neuropil, the link segment at

FIGURE 7 A 10 μ section of a cockroach metathoracic motor neuron innervating the extensor tibia muscle. The cell has been injected with the fluorescent dye Procion Yellow. The cell body (cb) is approximately 30 μ in its longest dimension.

Note the expanded integrating segment and the fine branches of the dendritic tree emanating from it. (From Rowe and Cohen, in preparation.)

best permits some electrotonic spread of neuropil activity to reach the soma. In many neurons, however, the resistance of this region is apparently so high that no electrical sign of synaptic or propagated activity is detectable in the cell body.

THE INTEGRATING SEGMENT The expansion of the 5–10- μ link segment into the 10–30- μ region giving rise to branches of the dendritic tree has been pictured in earlier work on arthropod central neurons (Zawarzin, 1924). It has been suggested that this area may serve as an integrating region (Maynard, 1966). However, its full significance as a struc-

tural and functional entity has only recently been realized and most elegantly defined in the crab by Sandeman (1969a, 1969b). He has termed this region the *integrating segment* and has studied it in detail both structurally and with intracellular recording. He finds the membrane of this segment to be electrically inexcitable, as judged by the decreasing amplitude of invading antidromic spikes. The side branches of the integrating segment conduct propagated spikes, which then evoke depolarizing excitatory potentials in the integrating segment. The presynaptic inhibitory input, which produces slightly depolarizing potentials in the integrating segment, appears to end directly on the

FIGURE 8 A reconstruction of a cockroach metathoracic motor neuron innervating the extensor tibia muscle. The cell was injected with Procion Yellow and reconstructed

from 10 μ serial sections. Diameter of cell body, approximately 30 μ . (From Rowe and Cohen, in preparation.)

membrane of this segment rather than on the fine branches emanating from it. The spike-initiating locus appears to be at the point where the integrating segment once again narrows distally to give rise to the axon proper. Figure 11 (page 808) summarizes the findings of Sandeman for an oculomotor neuron of the crab.

The integrating segment of the arthropod neuron, together with its fine, branching neurites, appears to be analogous to the soma-dendritic complex of the vertebrate neuron. Both anatomical entities have areas of electrically inexcitable membrane (Grundfest, 1969). They integrate excitatory and inhibitory presynaptic input that gives rise to a propagated signal at a spike-generating locus distal to the integrating membrane. The soma-dendritic complex of the vertebrate neuron places the genetic apparatus and the major site of macromolecular synthesis directly in the path of chemical transmitters and ionic changes associated with synaptic transmission and impulse initiation. In contrast, the arthropod central neuron isolates the soma with its genetic apparatus from the electrochemical events of synaptic and propagated activity. This isolation is such that in many neurons the soma reflects little or no electrical sign

FIGURE 9 Model of a second-order sensory interneuron from the sixth ganglion of the crayfish. Note the long tenu-

of events occurring in the distant integrating and spikegenerating regions.

Cytological comparisons

The cytoplasmic basiphilic masses characteristic of many vertebrate central neurons (Figure 12, page 809) were first described by Nissl (1892). These Nissl bodies were later found to be composed of layers of rough endoplasmic reticulum (Palay and Palade, 1955). Their basiphilia is presumably due to the affinity of the ribosomal RNA in these structures for such classic basic dyes as cresyl violet and toluidine blue (Bodian, 1947). The response of vertebrate neurons to injury of their axons consists of a breakdown of these basiphilic masses (chromatolysis) within the first week after injury, as seen in Figure 12B (Nissl, 1892; Bodian and Mellors, 1945). This may also be accompanied by a shift of the nucleus to an eccentric location within the soma. If the neuron survives and regenerates an axon, there may be a gradual re-formation of the Nissl bodies; the nucleus eventually returns to a central location.

In contrast, when the central neuron of a normal adult cockroach is stained with basic dye, it shows a fine-grained

ous link segment joining the cell body to the dendritic tree. (From Selverston and Kennedy, 1969.)

uniform distribution of basiphilic material throughout its cytoplasm, as seen in Figure 12. This is correlated with a scarcity of rough endoplasmic reticulum and a relatively uniform distribution of ribosomes throughout the cytoplasm (Hess, 1960; Wigglesworth, 1960; Cohen, 1967a).

Examination, in the electron microscope, of the perinuclear RNA ring evoked by injury to the axon of the cockroach central neuron reveals that this is associated with an increase in rough endoplasmic reticulum (rough ER). This is shown in Figure 13 (page 810), which compares the distribution of rough ER in a bilaterally symmetrical pair of cockroach motor neurons from the same ganglion. There is a generalized increase of rough ER in the injured cell, with some concentration in the perinuclear area. The cytoplasm of the injured cell takes on the appearance of a crudely organized Nissl body in a vertebrate. Within one week, the augmented rough ER of the injured cell disappears, and the nucleus shifts to an eccentric position, as seen in Figure 12D. At this time the injured neuron starts to regenerate a new axon. The disappearance of the rough ER in the cockroach cell appears similar to vertebrate chromatolysis, when the ribosomes become dissociated from the cisternae of the rough ER (Porter and Bowers, 1963).

FIGURE 10 Procion Yellow injected cell from the cockroach metathoracic ganglion. This is cell number 3 as designated in Figure 6. A: 10 μ section showing the cell body (cb) with the link segment (ls) emanating from it. B: The next 10 μ section shows the thin link segment expanding into the broad integrating segment (is). The longest dimension of the cell body in A is approximately 80 μ . (From Rowe and Cohen, in preparation.)

FIGURE 11 A diagram illustrating the various functional and morphological regions of an oculomotor neuron in the brain of a crab. Note the separation of the soma from the integrating region of the cell. The different modes by which excitatory and inhibitory input may terminate upon the cell are clearly shown. (From Sandeman, 1969b.)

The vertebrate neuron appears to be continually primed and involved in a relatively high level of protein synthesis (Hydén, 1960). This is associated with large amounts of rough ER characteristic of other actively synthesizing cells. The precipitous breakdown of rough ER, together with the dispersion of ribosomes in the vertebrate cell undergoing chromatolysis, is seen as throwing the cell into a superactive state of synthetic activity associated with axon repair (Brattgård et al., 1957). The intact central neuron of a cockroach differs from the central nerve cell of a vertebrate in lacking large aggregates of rough ER. This may be associated with a lower state of readiness for and participation in macromolecular synthesis. Only when extraordinary synthetic demands are placed on the cockroach neuron, as in axon regeneration, does this cell produce a crude approximation of the vertebrate neurocytological organization. It does so by first forming rough ER and then dispersing it in a manner similar to the chromatolysis response of the vertebrate nerve cell. Such arthropods as the crayfish (Hoy et al., 1967) and the locust (Usherwood, personal communication) do not show the type of axonal regeneration described for the cockroach (Bodenstein, 1957) and the vertebrate (Bodian, 1947). The neurons of these animals do not show the perinuclear RNA ring response to injury. Other invertebrates, such as the cricket (Edwards and Sahota, 1967) and the mollusk Anodonta (Salánki and Gubicza, 1969), show typical axon degeneration and regeneration following injury, and their central neurons have the perinuclear RNA ring response. This substantiates the concept that the formation and subsequent dispersion of the rough ER in the perinuclear ring are associated with an increase in the level of macromolecular synthesis associated with axon regeneration.

Functional considerations

A major structural difference between the central neurons of invertebrates and those of vertebrates is the almost ubiquitous occurrence of monopolar neurons in the invertebrate groups above the Coelenterata (Bullock and Horridge, 1965). In contrast, the vertebrate central neuron is predominantly multipolar and heteropolar. It is divided into an integrating soma-dendritic complex and an axon that generates an all-or-none signal. At the unit level, a primary functional consequence of these differences is that the soma of the invertebrate central neuron, unlike that of the vertebrate cell, is removed from the path of synaptic transmission and impulse initiation.

Let us make the assumption that in neuronal systems specialized to store and reflect a sign of their functional history, such storage and reflection may be accomplished by coupling the bioelectrical signals to the genetic apparatus of the soma. This provides the possibility that some aspects of the transient electrochemical signals may be reflected more permanently in the neuron by an alteration in macromolecular synthesis (Hydén, this volume). Several lines of evidence from cells other than neurons suggest that the type of bioelectrical events associated with neuronal signals may affect the synthesis of macromolecules. In the salivary-gland chromosomes of Chironomus, Kroeger (1966) has demonstrated a correlation between "puffing" and the degree of depolarization of the gland-cell membrane. The insect growth hormone ecydysone also has an effect on the ion permeability of the nuclear membrane in the salivary gland cells of Chironomus (Ito and Loewenstein, 1965). Lubin (1967) reports a decrease in the rate of DNA and protein synthesis in cultured mammalian cells when the potassium concentration is lowered. Thus the tendency to isolate the invertebrate central nerve-cell body from the transient ionic and transmitter fluxes associated with information processing may be viewed as a means of stabilizing the function of neuronal circuits over the lifetime of the organism. This could account for a major evolutionary trend among the invertebrates that has taken the direction of relatively complex but highly stereotyped behavior.

The isolation of the neuronal soma in invertebrates may also allow the control of such complex but rigid behavioral patterns as flight, walking, and swimming to be reliably invested in very small numbers of neurons. Kennedy et al. (1969) described single command interneurons in the crayfish that control the activity of large segments of abdominal musculature involved in swimming. Willows (1967) has shown that stimulating a single central neuron can evoke the turning of the entire body of a sea snail.

The Mollusca provide a major exception to the concept that the central-neuron soma of invertebrates is relatively isolated from the bioelectric activity of the cell. In the sea

FIGURE 12 A comparison of injury responses in central neurons of a rhesus monkey (A and B) and a cockroach (C and D). A: Normal ventral horn cell, showing the basiphilic aggregates of Nissl bodies in the cytoplasm. B: Ventral horn cell seven days after lumbar spinal-root section. Chromatolysis is indicated by the absence of Nissl bodies and the eccentric location of the nucleus. C and D are bilaterally matched cells from the same metathoracic ganglion. C:

Normal cell, showing a uniform cytoplasmic basiphilia and a centrally located nucleus. D: Cell axon was cut four weeks prior to fixation. The distribution of basiphilic material in the cytoplasm is unchanged, but the nucleus has assumed an eccentric position. (Plate from Cohen, 1967a. A and B modified from Bodian and Mellors, 1945; C and D from Cohen and Jacklet, 1967.)

snail *Aplysia*, the site of spike initiation may be as much as 1.5 mm from the soma (Frazier et al., 1967). Although the membrane excitability decreases from the site of spike initiation proximally toward the cell body, overshooting spikes can frequently be recorded from the soma (Tauc, 1962). More highly evolved members of the group, such as

the cephalopods, are capable of complex rapid learning, particularly within a visual framework. Young (1964) summarized many of the behavioral studies in *Octopus* and correlated these with the anatomy of the brain and visual system. His drawings of silver preparations in the optic lobe of *Octopus* indicate cells that are multipolar and heteropolar.

FIGURE 13 Tracings of montages made from electron micrographs taken at 17,000 magnification. The shaded area indicates endoplasmic reticulum and free ribosomes. A and B are tracings from a pair of bilaterally matched motor neurons situated on opposite sides of the same metathoracic ganglion in the cockroach. The cells were approximately 35μ in diameter and roughly one half of each cell is pictured. n, nucleus; nm, nuclear membrane. A: normal cell with intact axon. B: matched cell whose axon was cut 48 hours previous to fixation. Note the increased amount of endoplasmic reticulum in the injured cell. (Modified from Young et al., in press.)

These neurons, such as the centrifugal cells, appear to have dendritelike processes emanating from the soma. This is one of the few instances of multipolar-heteropolar nerve cells reported in the central nervous system of an invertebrate. The more primitive mollusks, such as *Aplysia*, have neurons whose somata are both electrically excitable and sensitive to synaptic transmitters (Tauc and Gershenfeld, 1961). These may have been crucial requisites in the evolution of the extraordinary labile and modifiable behavior shown by the Cephalopoda. Based on the prime characteristic of soma excitability, the appearance of dendritic expansions from the soma places the neuronal genetic apparatus of the Cephalopoda subject to the electrochemical events of transmission and conduction. It is of more than passing interest that this type of neuron appears in the invertebrate group with the most highly evolved type of modifiable behavior, and in that part of the nervous system shown to be intimately involved in the learning process.

In the vertebrates, the body of the central nerve cell has been thrust directly into the path of the electrochemical changes associated with information processing. The elements controlling macromolecular synthesis within the soma are thus exposed to fluxes of inorganic ions and chemical transmitters that may influence their function and provide some long-term sign of past activity in the form of a macromolecular residue. Another major advance in the neural organization is the relatively large number of neurons available in vertebrates as compared with invertebrates (Wiersma, 1952; Bullock and Horridge, 1965). This can provide the segments of the nervous system involved in low-threshold, highly plastic behavior with the degree of redundancy required to function in a reliable and adaptively significant manner. These two factors, (1) the exposure of the genetic apparatus to the electrochemical events of signal processing and (2) relatively large numbers of neurons, may have been critical in the evolution of the extraordinary plastic capabilities characteristic of the most highly developed portions of the vertebrate central nervous system.

71 Some Aspects of Gene Expression in the Nervous System

E. M. SHOOTER

THE PRIMARY INSTRUCTIONS for the development of the nervous system in terms of cell specialization, cell migration, and the formation of intercellular connections are located in the genome and give rise to patterns of innate behavior. The programing of these events is fortunately not on a one-toone basis. On the contrary, it is evident that the behavior of whole cell populations is dictated by single genes. In the neurological mutant mouse strain, reeler, which is homozygous for the allele rl, the granule cells fail to migrate normally inward through the Purkinje cells of the cerebellum (Sidman, 1968). Not only does this mutation affect the majority of the granule cells; it also affects the only other two neuroblast populations, those in the cerebral isocortex and the hippocampus, which migrate in the same way. The altered gene product of the allele rl results, therefore, either directly or indirectly, in the failure of the cell-to-cell signaling required for normal migration. It is also clear that throughout development internal and external environmental factors continue to modify gene expression in the nervous system and that, in turn, variable gene expression is likely to be one of the neural components that are the basis of learning.

This brief introduction illustrates the two general ap-

proaches to the study of gene expression in the nervous system I discuss here. First, one can examine the primary products of gene action, the proteins and enzymes of neurons and glia, follow their changing patterns during development, and delineate the consequences of mutations. Alternatively, one can see how internal stimuli such as hormones and growth factors modify or regulate gene expression in the target cells. These two categories are not exclusive and do overlap. For instance, the selective regulation of neuronal activity by hormones requires that these cells be able to distinguish between such inducers. One way to study this is through the analysis of nerve-cellspecific macromolecules, the primary product of the gene action of those cells.

The primary products of gene action

SITES OF PROTEIN SYNTHESIS Because of the unusual morphology of nervous-tissue cells compared with other eukaryotic cells, it is important to consider the sites within these cells at which protein may be synthesized. In addition to the usual ribosomal and mitochondrial protein-synthesizing systems, two other possible systems, the synaptosomal and axonal, should be considered.

RIBOSOMAL PROTEIN SYNTHESIS In large neurons, the cytoplasmic ribosomes are concentrated near the endoplasmic reticulum of the Nissl substance in the perinuclear

E. M. SHOOTER Departments of Genetics and Biochemistry and the Lt. Joseph P. Kennedy, Jr. Laboratories for Molecular Medicine, Stanford University School of Medicine, Stanford, California

region, the initial segment, and the axonal hillock (Sotelo and Palay, 1968). A high proportion of these ribosomes are not attached to the membrane of the endoplasmic reticulum and could thus function directly in the synthesis of protein involved in axoplasmic transport to the nerve ending (see Weiss, Davison, this volume). The membranebound ribosomes, on the other hand, are probably involved in the synthesis of proteins for storage in the cell or of conjugated proteins. In many smaller neurons, Nissl bodies and ribosomes appear in the most peripheral cytoplasm, underlying either synaptic terminals (Bodian, 1965) or neuroglial processes adjacent to the surface of the neuron. In contrast, in glia, as in other eukaryotic cells, the ribosomes are more evenly distributed through the cytoplasm, and a greater proportion are bound to the endoplasmic reticulum (Mugnaini and Walberg, 1964). Glia contain less RNA than do neurons, which appears to be directly related to the ribosomal content of the two types of cells (Hydén and Egyházi, 1963; Gray, 1964). Recent reports suggest that glial ribosomes are as active as neuronal ribosomes in protein synthesis (Roberts et al., 1970).

A ribosomal preparation from immature rat brain has many of the characteristics of typical mammalian ribosomal systems in its requirement for pH 5 enzymes and adenosine triphosphate (ATP) and its inhibition by ribonuclease (Campbell et al., 1966). Its activity is higher than that of a similar liver preparation, although the activity decreases significantly with the age of the animal (Orrego and Lipmann, 1967). The level of activity will depend on, among other factors, the availability of the initiating, binding, translocation, and dissociation factors now defined for the bacterial ribosomal system (see Davis, this volume) and about which little is known in the nervous system. Maximum incorporation with the brain ribosomal system occurs at somewhat higher Mg^{2+} concentrations than with liver or reticulocyte preparations (Table I). Although mammalian ribosomal systems, in general, are more resistant to such agents as high Mg²⁺ concentrations, which increase ambiguity in translation (Weinstein et al., 1966), it is not known whether this is also true for brain ribosomes. The requirement of the latter for high K⁺ concentrations links ribosomal protein synthesis with active K+ transport and, in turn, with the bioelectric phenomena. Zomzely et al. (1968) have reported that polysome-mRNA complexes from brain are more sensitive to endogenous ribonuclease than is a liver preparation, release endogenous mRNA more readily on incubation, and correspondingly show a greater stimulation on subsequent addition of polyuridylic acid (poly-U). Nuclear RNA from brain is more active in stimulating an E. coli ribosomal system than is hepatic nuclear RNA, contains a high proportion of small (i.e., < 12S) species, and has a higher turnover rate in young than in adult animals, giving rise to the suggestion that, during development, relatively short-lived mRNA species with high template activity are replaced by longer-lived species with a lower activity (Roberts et al., 1970; Bondy and Roberts, 1968).

MITOCHONDRIAL PROTEIN SYNTHESIS Mitochondria contain their own machinery for protein synthesis (see Lehninger, this volume), and, although mitochondrial protein synthesis is quantitatively less significant than ribosomal, it is especially important in the nervous system because of the presence of mitochondria in nerve endings and the question of local protein synthesis in these regions. It is, therefore, of even greater interest that brain mitochondria are among the most active of the known mammalian mitochondrial systems (Campbell et al., 1966). Protein synthesis by brain mitochondria does not require an external source of ATP and is not inhibited by ribonuclease, but, typically, is inhibited by chloramphenicol. In a medium that is optimal for oxidative phosphorylation, incorporation increases by a factor of ap-

proximately two (Table I) to a level that is about one tenth that of ribosomal incorporation. Conversely, under these conditions, incorporation is inhibited by substances like rotenone and antimycin A, which are specific inhibitors of oxidative phosphorylation. The DNA in mitochondria is of limited size and is potentially capable of coding for only about 40 polypeptides, each of 150 amino acid residues. In keeping with this are the reports that mitochondria synthesize very few proteins, among which are certain of their own membrane proteins (Neupert et al., 1968). However, the fact that Neurospora mitochondria can synthesize protein in vivo (see Lehninger, this volume), suggesting the rather massive synthesis of a few specific proteins, prompts a re-examination of the role of both cell-body and nerveending mitochondria in the synthesis of extra-mitochondrial protein. Not all mitochondria are alike, those in the nerve ending being typically smaller than those in the cell body. Also Hajós and Kerpel-Fronius (1969a, 1969b) have now shown by electron histochemical techniques that mitochondria that are some distance from the cell body, particularly those in certain postsynaptic regions and unlike those in the perikarya, lack the enzyme succinic dehydrogenase and accumulate considerably less Ca⁺ and Sr²⁺. Similar differences can be detected in isolated mitochondrial pellets. This type of biochemical differentiation may well be of critical importance to the functions of mitochondria in various regions and sites of the nervous system.

SYNAPTOSOMAL PROTEIN SYNTHESIS The studies of Weiss (this volume) and Barondes (1966), among others, have shown that at least a portion of the mitochondrial and vesicular proteins (if not also whole mitochondria and vesicles) in the nerve endings derive from the cell body. It is also true that some protein in nerve-ending organelles and membranes is rapidly labeled, in vivo after intraventricular or intraperitoneal injection of radioactive amino acids (von Hungen et al., 1968), in vitro in brain slices (Austin and Morgan, 1967), or in vitro in isolated ciliary ganglia (Droz and Koenig, 1969), and the question arises as to where this particular protein is synthesized. Attempts to answer this question have been made by examinations of the metabolic properties of isolated synaptosomes (Autilio et al., 1968; Morgan and Austin, 1968; Gordon and Deanin, 1968) and axons (Koenig, 1970). Isolated synaptosomes incorporate labeled amino acids into protein at very low levels, as compared with brain ribosomes (Table I.) Bacterial contamination has been excluded, as has also contamination by free neuronal or glial microsomes or ribosomes, because the system is not sensitive to ribonuclease and does not require ATP. Furthermore, labeled brain microsomes separate quantitatively from synaptosomes in the preparative gradients used to isolate the latter (Austin and Morgan, 1967). The data of Autilio et al. (1968) and Austin et al. (1970) have shown that only a portion of the protein-synthetic capacity of the synaptosome is due to synaptosomal mitochondria. In the presence of chloramphenicol, total incorporation is reduced to only about 75 per cent of control, whereas incorporation into mitochondrial protein, but not into soluble or other membrane protein, is almost totally inhibited (Table II). Conversely, cycloheximide markedly reduces total incorporation and incorporation into soluble and nonmitochondrial membrane protein but does not inhibit protein synthesis in synaptosomal mitochondria. In line with these results is the finding (Autilio et al., 1968) that some 20 per cent of the label is normally incorporated into the soluble protein of the synaptosome, 25 per cent into mitochondrial protein, and the remainder into nonmitochondrial membrane protein.

A characteristic feature of synaptosomal protein synthesis is its synergistic stimulation by appropriate concentrations of Na⁺ and K⁺ (Table I). The ionic concentrations required for maximal incorporation also result in maximal sodiumpotassium adenosine triphosphatase activity, K⁺ uptake, and oxygen uptake (Appel et al., 1969; Escueta and Appel, 1969; Morgan and Austin, 1969; Austin et al., 1970). It may be noted that these concentrations are quite different from those required for maximum incorporation with the brain ribosomal system (Table I). Inhibition of the sodium-potassium adenosine triphosphatase activity by ouabain also markedly inhibits synaptosomal protein synthesis. These

Antibiotic	Incorporation as percentage of control into			
	Whole synaptosome	Soluble protein	Membrane protein	Mitochondrial protein
Puromycin, 50 µM	24	35	31	23
Cycloheximide, 100 µM	29	13	27	92
Chloramphenicol, 300 µM	74	98	91	5

* Adapted from Austin et al., 1970.

results not only suggest a unique character for synaptosomal protein synthesis, but also point to a close coupling of the synthetic activity with ionic flux and energy metabolism in the nerve ending. There remains the problem of the mechanism of protein synthesis in the nerve ending other than in the mitochondria. The presence of both RNA and enzymes that activate amino acids has been reported (Austin et al., 1970), and the mechanism is certainly sensitive to cycloheximide, a known inhibitor of mammalian ribosomal protein synthesis. In one way, these findings again raise the problem of contamination, possibly by elements of the ribosomal system which enter the synaptosome before membrane closure or which remain outside the synaptosome but are also membrane enclosed. At least a part answer to this has been given by the demonstration that the pattern of labeling of proteins in a microsomal system is grossly different from that in the synaptosome (Autilio et al., 1968), and a final answer may be available when it is known specifically which proteins are synthesized in the nerve ending.

Axonal protein synthesis The evidence for local protein synthesis by axons has been reviewed by Koenig (1970). Myelin-free axons will incorporate labeled RNA precursors into an acid-insoluble product, a major portion of which is digested by ribonuclease. This RNA does not appear either to be mitochondrial in origin or to be transferred from the Schwann cell to the axon (Koenig, 1969). The amount of RNA present in axons is, however, extremely small—1/500th to 1/1000th of that in the cell body. As with the synaptosomal system, a more rigorous demonstration of the synthetic capacity of axons will come from the identification of the products of this activity.

Identification of the primary products and their function

If a protein possesses some catalytic or specific biological or physical property, it can be identified and the regulation of its synthesis can be followed with the aid of that particular property. McKhann and Ho (1967) have shown, for example, that the development pattern of the enzyme galactocerebroside sulfatransferase, responsible for the last step in the biosynthesis of the myelin lipid sulfatide, parallels that of myelination. Again $D(-)=\beta$ -hydroxybutyrate dehydrogenase, the activity of which is high in developing brain but low in adult brain, can be induced in the latter by starvation, enabling the adult brain to use an alternate oxidizable substrate (Smith et al., 1969b). There are also many examples of altered gene function in the nervous system, as expressed in the behavior of enzymes, some of which give rise to disease states. Here the effect of a mutation in a catabolic enzyme is equally as dramatic as that in an anabolic enzyme, as is shown in metachromatic leucodystrophy by the accumulation of large amounts of a normal component of the myelin sheath, sulfatide, as a result of the functional absence of an arylsulfatase catabolic enzyme (Mehl and Jatzkewitz, 1965).

Changes in the number and composition of brain-membrane proteins arising from the modification of gene expression during development can now also be followed (Grossfeld, 1968). With increasing age in the mouse a greater preponderance of species with higher molecular weight appears (Figure 1); these may result from modification of the original proteins with carbohydrate or other prosthetic groups or from the shift from a neuronal to a largely glial cell population. Mahler and Cotman (1970) have shown that these or similar methods can be used to characterize the proteins of the membranes of nerve endings.

NERVOUS SYSTEM SPECIFIC PROTEINS Nerve cells obviously have unique function compared with other cells. Gene activity in nerve cells subserves these functions; it is therefore possible to learn about gene activity by searching out and studying its unique products.

Brain extracts contain a number of relatively acidic proteins that do not appear in extracts of other organs, and two of these, S100 and 14-3-2, have now been shown by immunological criteria to be specific to the nervous system (Moore and Perez, 1968). Antiserum to beef brain S100 cross-reacted with brain extracts from all vertebrates and some invertebrates, and antiserum to 14-3-2 reacted with extracts from all vertebrates except fish and reptiles, so they appear to have a high degree of evolutionary stability and thus, presumably, an important function. Because of its presence in cultured gliomas (Benda et al., 1968) but not in cultured neuroblastomas, its high content in cerebral white and low content in cerebral gray matter, and a constant or slightly increased amount in degenerating optic nerve, S100 is thought to be localized primarily in glia (Moore and Perez, 1968). By similar criteria, 14-3-2 is a neuronal protein. A possible clue to the function of S100 comes from studies of its interactions with calcium, sodium, and potassium ions (Calissano et al., 1969). The S100 protein specifically binds two calcium ions, resulting in local unfolding of the structure. Other divalent ions, such as magnesium, do not produce this conformational change, although potassium and, to a lesser extent, sodium ions tend to inhibit the effect. In so doing they insure that the conformational change occurs in the range of calcium-ion concentration that probably exists in the nervous system. The protein 14-3-2 does not bind calcium ion, has a higher molecular weight than \$100, and appears to exist also in polymeric forms. Antigen α , the soluble protein specific to the nervous system that was isolated by Bennett and Edelman (1968), is unrelated by immunological or chemical

FIGURE 1 Developmental changes in membrane proteins from mouse brain. Mouse brains from animals of different ages extracted with 1 per cent Triton X-100 in 0.01 M tris-Cl buffer pH 8.1. Residue extracted with 0.1 per cent sodium dodecyl sulfate in the same buffer with sonication. These extracts dialyzed against 0.025 per cent sodium

dodecyl sulfate in the same buffer and applied to polyacrylamide gels. Electrophoresis was carried out in the tris glycinate discontinuous buffer system, pH 9.6, with 0.025 per cent sodium dodecyl sulfate in all solutions. Stained after electrophoresis with Naphthol Blue Black (Grossfeld, 1968).

criteria to \$100 protein, but it forms aggregates stabilized by disulfide bonds as does protein 14-3-2.

Myelin also contains a number of specific proteins, including a 165-residue basic protein responsible for the encephalitogenic activity of nervous-system tissue (Eyhlar and Hashim, 1969). Smaller fragments derived from it by the action of a brain acid protease or pepsin also have the activity, and the sequence of one of these has been reported (Eyhlar and Hashim, 1969; Kibler et al., 1969). Other myelin proteins are the proteolipid proteins described by Folch and Lees (1951) and Wolfgram (1966). These three groups have a functional role in the maintenance of the myelin membrane.

Modification of gene expression

Both internal factors, such as hormones and growth factors, as well as external stimuli regulate gene expression during development of the nervous system. One of the bestknown examples of such agents is the nerve growth factor (NGF), discovered and studied extensively by Levi-Montalcini and her colleagues (Levi-Montalcini and Angeletti, 1968). The nature of this growth factor and of its mechanism of action is obviously of great interest as a model system for the study of the modification of neuronal behavior. NGF stimulates the growth of sympathetic and sensory ganglia in chick embryos or young mice, producing marked increases in the size of the responsive neurons and in fiber outgrowth from such neurons. If chick sensory or sympathetic neurons of appropriate age are cultured in a hanging drop of semi-solid plasma containing optimum concentrations of NGF, a uniform and dense halo of nerve fibers grows out from the ganglia. The varying degree of fiber growth under these conditions in response to differing amounts of NGF forms the basis of a bioassay for this factor (Levi-Montalcini et al., 1954).

Antiserum to NGF inhibits the activity of NGF in the tissue culture assay, and when it is injected into newborn animals of several species it causes a rapid and almost complete destruction of the nerve cells in the sympathetic ganglia (Cohen, 1960; Levi-Montalcini and Booker, 1960). The first property of the ganglia to be affected in vivo is that of electrical transmission, the action potential being markedly depressed a few hours after injection and before significant changes take place in either metabolic function or ganglion size (Halstead *in* Larrabee, 1969, p. 108).

THE MACROMOLECULAR STRUCTURE OF NGF What is the nature of the factor that produces these specific growth effects? It has been shown that in the two common sources of this material, snake venom and the adult mouse submaxillary gland, NGF activity is associated with protein (Cohen, 1959, 1960). Subsequent work confirmed these initial observations and showed that it was possible to isolate, from either source, small, rather basic proteins that had NGF activity (Cohen, 1959, 1960; Varon et al., 1967a; Angeletti, 1968; Banks et al., 1968; Zanini et al., 1968). It is now clear, however, that these basic proteins are derived, as a result of the isolation procedure, from larger protein species that exist in both venom and extracts of the mouse gland. The macromolecular composition of these larger species is therefore of considerable interest in relation to their role in stimulating neuronal growth.

In the submaxillary gland extracts, the biologically active basic protein is only one type of subunit, the β subunit, in a multisubunit protein, 7S NGF (Varon et al., 1967b, 1968). 7S NGF, which elicits the same in vivo and in vitro effects as the smaller basic protein, can be isolated from the gland in a reasonable degree of homogeneity (Figure 2A), and its subunit composition can be demonstrated by its reversible dissociation at extremes of pH. This process is readily visualized by the isoelectric focusing procedure when 7S NGF is dissociated by applying it to the acidic end of the pH gradient in the gel (Figure 3b). The undissociated 7S NGF can also be analyzed by the same procedure if it is initially applied near the center of the gradient, and its isoionic point lies between the isoionic points of the α and γ sub-units (Figure 3a, c). The three groups of subunits are separable by ion-exchange chromatography and show the same distribution of protein species within each group after isolation (Varon et al., 1968; Smith et al., 1968). The analysis of isolated β subunits is shown in Figure 3d as an example. The separated subunits recombine rapidly when mixed at neutral pH and in appropriate amounts to regenerate a protein the physical properties of which are the same as those of 7S NGF (Figure 2).

The specific biological activity of the β subunit isolated from 7S NGF at acid pH is similar to that of 7S NGF but is somewhat higher when isolated from the penultimate material in the 7S NGF preparation (Varon et al., 1968). Both Zanini et al. (1968) and Fenton and Edwards (quoted in Vernon et al., 1969) also reported that the specific

FIGURE 2 Comparison of the sedimentation and electrophoretic properties of 7S NGF and the product of the recombination of α , β , and γ subunits. A. Sedimentation of 200 µg 7S NGF or a mixture of 72 µg α , 118 µg γ , and 42 µg β subunits mixed in 0.05 M tris-Cl buffer (pH 7.4). Sed-

imentation was for 13 hours at 60,000 rpm in a 5–20 per cent sucrose gradient in 0.05 M tris-Cl buffer (pH 7.4) at 5° C. B. Electrophoresis in the bistris-tes buffer system (pH 7.55) of 150 μ g 7S NGF and a mixture of 60 μ g a, 78 μ g γ , and 35 μ g β subunits in 0.05 M tris-Cl buffer (pH 7.4).

FIGURE 3 Isoelectric focusing of 7S NGF and its subunits. A. 7S NGF applied near center of gel. B. 7S NGF applied at top. C. 7S NGF applied at top and near center. D. β subunit isolated by chromatography at acid pH. E. β subunit

activity of the β subunit (NGF, in the terminology of the former authors), isolated by the same procedure but by using milder acid conditions, is higher than that of 7S NGF. The biological activity of the β subunit is therefore modified by its interaction with the α and γ subunits, and both biologically inactive subunits are required to produce this specific effect with the β subunits (Varon et al., 1968) as they are to produce 7S NGF. The 7S NGF protein also exhibits esterase or peptidase activity relatively specific for argininyl esters or amides, an activity that resides only in the γ subunits, and likewise the specific enzymatic activity of these subunits is modified (decreased) by its interaction with the α and β subunits (Greene et al., 1969). Again, both of the subunits are obligatory for this effect (Table III). The biological and enzymatic properties of 7S NGF reconstituted from the three subunits are identical to those of the original 7S NGF preparation, and, in particular, the lagphase enzyme kinetics characteristic only of the latter reappear upon the aggregation of the three subunits (Greene et al., 1968). Other evidence that pertains to the specificity of the interaction of the three subunits is summarized by Shooter and Varon (1970).

Although 7S NGF migrates as a single band on electrophoresis, it is actually a family of 7S proteins, each com-

isolated by chromatography at alkaline pH. The acrylamide gels were 7.5 per cent made in the ampholine buffer system pH 3–10. After electrophoresis they were stained with Coomassie Blue.

posed of the same number of α , γ , and β subunits but differing in the type of α or γ subunits they contain (Smith et al., 1969a). It is the dissociation of these multiple forms of 7S NGF that produces the variety of individual α and γ subunits (Figure 3). Furthermore, these multiple 7S NGF proteins are in equilibrium with one another through an exchange of free α subunits (Smith et al., 1969). This may be demonstrated in the observation that ¹²⁵I-labeled α sub-

TABLE III The Effect of the α and β Subunits of 7S NGF on the Enzymatic Activity of the γ Subunit

Subunits	Relative enzymatic activity*	
γ	1.00	
$\gamma + \beta$	0.99	
$\gamma + \alpha$	1.10	
$\gamma + \alpha + \beta$	0.20	
	(lag-phase kinetics)	

* Enzymatic activities are given as ratios of the activity of each mixture to that of the γ subunit alone. Activity was measured with 1.0 mM benzoyl arginine ethyl ester in 0.05 M tris-Cl buffer (pH 7.0). (Adapted from Greene et al., 1969.)

units are incorporated into 7S NGF when mixed with the latter at neutral pH, or by the appearance of all the individual α subunits in the free subunit pool when an excess of any one α subunit, e.g., the α^2 subunit, is again added to 7S NGF. It follows that the time lag observed before 7S NGF hydrolyzes appropriate substrates at maximum rate is caused by the time required for the dissociation equilibrium of 7S NGF to re-establish itself at a new equilibrium position after dilution for the assay, the principal enzymatic species being the uncomplexed forms of the γ subunits (possibly $\gamma\beta$ complex, although other species are possible) rather than 7S NGF itself. Conversely, the lag can be eliminated if the diluted 7S NGF solution stands for some time before the substrate is added, which allows 7S NGF to dissociate.

The basic NGF protein, separated by Zanini et al. (1968), which has the physical properties of the β subunit, on standing in dilute solution apparently disaggregates into half molecules that give identical immunodiffusion and electrophoretic patterns and complement fixation curves. That dissociation of the β subunit of 7S NGF can take place is demonstrated by its behavior on electrophoresis in the presence of sodium dodecyl sulfate. In line with previous sedimentation data, both α and γ subunits migrate as single bands in positions corresponding to a molecular weight of about 30,000 (Figure 4). 7S NGF dissociates completely in this solvent and also, as expected, gives a major band in the same position as the subunits; in addition, a faster minor band appears, which can arise only from the dissociation of the β subunit (Figure 4). Analysis of a β subunit isolated by chromatography at alkaline rather than at acid pH (Figure 3E) also demonstrates how derivatives of this subunit of differing isoionic points can arise under various conditions.

A recent method for isolating NGF from Crotalus adamanteus venom (Angeletti, 1968) closely parallels the one devised for the mouse gland NGF (Varon et al., 1967b) and suggests that NGF aggregates in the venom have molecular weights lower than that of 7S NGF. However, a major final product is still a basic protein similar in size and electrophoretic properties to the β subunit of 7S NGF. Another component is a basic protein about half of the size and identical to the major component in amino acid composition and immunochemical properties (Levi-Montalcini and Angeletti, 1968). Immunochemical analysis confirms that the NGF basic protein from venom is structurally related to the β subunit from the mouse gland (Zanini et al., 1968). Using an alternate isolation procedure, Banks et al. (1968) obtained from the venom of Vipera russelli a basic protein, homogeneous by sedimentation analysis, although not by other criteria, and of molecular

FIGURE 4 Molecular size and composition of the subunits of 7S NGF. 7S NGF (100 μ g) or the α and γ subunits (30 μ g) were subjected to electrophoresis in acrylamide gels in 0.1 M phosphate buffer (pH 7.0) containing 0.1 per cent sodium dodecyl sulfate. The mixtures of standard proteins were made from 30 μ g each of γ globulin (γ -glob), bovine serum

albumin (BSA), ovalbumin (oval), chymotrypsinogen (chymo), and human adult hemoglobin (Hb). All proteins were denatured first in 1 per cent sodium dodecyl sulfate in the same buffer. Stained after electrophoresis with Coomassie Blue.

weight 40,000, with high NGF activity. The increase in biological activity of their preparation resulted only from ion-exchange chromatography on a strongly basic resin and exceeded the actual protein purification obtained in this step, so these authors suggest that NGF normally is associated with some other protein, removed in this particular step, which masks its intrinsic activity. The relationships of the various basic NGF proteins from venom remain to be clarified, as does the molecular composition of the larger NGF species in the venom itself.

Why is NGF activity in the venom and the submaxillary gland extracts associated with these subunit-containing or aggregated proteins, and what part do these extra proteins, e.g., the α and γ subunits, play in the molecular mechanisms that finally produce fiber outgrowth? It is well known that the β subunit or the small basic proteins from venom are alone sufficient to elicit the NGF effect and also, as mentioned earlier, that antibodies made against these species inhibit fiber growth in the bioassay in vitro and result in the destruction of ganglia in the sympathetic chain in vivo (Levi-Montalcini and Angeletti, 1966). Moreover, it is an apparent paradox that, although the NGF effect is elicited in vitro, at concentrations of 10-8 grams per milliliter, in which at least some subunit-containing proteins, e.g., oxyhemoglobin, are fully dissociated, it is still possible to distinguish between the level of activity of 7S NGF and that of the β subunit. The availability of ¹²⁵I-labeled 7S NGF makes it possible to determine which molecular species are present at those concentrations. Sedimentation analyses show that even at 10⁻⁸ grams per milliliter, more than 50 per cent of the protein is present at 7S NGF, suggesting a dissociation constant of approximately 10⁻¹⁰ -10⁻¹¹M (Smith, unpublished data). Although these experiments were performed at low temperatures and in dilute buffer solutions and do not relate directly to in vivo or bioassay conditions, they do demonstrate the remarkable stability of 7S NGF, a property it shares with at least one other protein, aspartate transcarbamylase (Schachman and Edelstein, 1966). In keeping with this, measurements of the rate of α subunit exchange and of the rate of association of the three subunits suggest that the rate of dissociation of 7S NGF is relatively slow even at elevated temperatures (Smith et al., 1969a). Thus the time required for 7S NGF to dissociate and re-establish a new equilibrium on dilution for enzymatic assay is of the order of 15 minutes at room temperature (Greene et al., 1969). As far as they go, the present data do not discount the possibility that 7S NGF functions as an entity in eliciting biological activity, which would be in keeping with the ability to distinguish biologically between 7S NGF and β subunits. Although it is clear that the biological and enzymatic activities of the β and γ subunits are modified by their interactions with the other subunits—that of the γ subunit to such an extent that it may be inactive in 7S NGF—there is no direct information as to what role the biologically inactive subunits may play in the growth-stimulating properties of NGF. It is of interest to note, however, that at least two other esteropeptidases have been shown to have effects on the growth of certain cells (Attardi et al., 1967; Grossman et al., 1969) and that thrombin, itself an esteropeptidase, exhibits an NGF-like activity (Hoffman and McDougall, 1968).

THE MECHANISM OF ACTION OF NGF The question of whether NGF acts to stimulate fiber outgrowth by directly affecting transcription of new mRNA has been examined in some detail. The earlier evidence, which argued in favor of the hypothesis, was the finding that, using sensory ganglia, NGF stimulated the incorporation of 3H-uridine in vitro prior to its effect on the incorporation of ¹⁴C-amino acids (Angeletti et al., 1965). The finding that actinomycin-D blocks the NGF effect on amino acid incorporation, while puromycin does not affect the NGF-induced increase of uridine incorporation into RNA, also fits in with the concept of a direct effect on mRNA synthesis, as does the observation that actinomycin-D fails to prevent the NGF stimulation of amino acid incorporation if the ganglia are pre-incubated with NGF. At the morphological level, the structural components of the nucleoli and nuclei alter under the influence of NGF, undergoing a process of condensation and separation into masses of different density and structure (Levi-Montalcini et al., 1968, 1969). On the other hand, attempts to detect increased mRNA synthesis by changes in the distribution pattern of labeled RNA or in RNA base ratios in the presence or absence of NGF have not been successful (Toschi et al., 1966; Burdman, 1967).

More recently, Larrabee and his colleagues (Larrabee, 1969) have emphasized that it is difficult to demonstrate unequivocally that NGF stimulates certain metabolic pathways in ganglia in tissue culture because of the known deterioration of control ganglia in the absence of NGF (Angeletti et al., 1964; Levi-Montalcini et al., 1968). When the oxidation of glucose by sympathetic ganglia is monitored continuously, it is found that NGF does not increase the utilization of the Cl of labeled glucose in the first few hours. The difference in Cl utilization only becomes significant after about five hours, by which time the Cl utilization in the control ganglia is actually falling (Figure 5). Thus these experiments may only be measuring the other known property of NGF, which is the preservation of cell viability (Levi-Montalcini and Angeletti, 1963), or they may be measuring both the better maintenance and increased growth. In addition, these workers have been able to demonstrate that increased fiber outgrowth is not necessarily dependent on increased RNA synthesis. Using sympathetic ganglia from 14-day-old chick embryos, they confirmed that actinomycin-D not only inhibits RNA syn-

FIGURE 5 Effect of NGF on the glucose metabolism of sympathetic ganglia. Release of labeled CO_2 from sympathetic ganglia excised from chick embryos and supplied with glucose labeled in various positions with ¹⁴C in the

presence and absence of NGF. The average output for carbons 2, 3, 4, and 5 was calculated by subtracting the output of C1 and C6 from the output with uniformly labeled glucose (Brown *in* Larrabee, 1969, p. 110).

thesis in control ganglia but eliminates the usual NGFinduced stimulation of RNA synthesis (Figure 6). In spite of the almost complete cessation of uridine incorporation over the entire incubation period, fiber growth, measured by the width of the fiber halo, was reduced by only about 25 per cent. Experiments with the protein synthesis inhibitor cycloheximide showed that this reduction in growth was attributable to the minor effect of actinomycin-D on protein synthesis. The converse of this situation holds in sympathetic ganglia from younger, nine- to 10-day-old embryos. Although RNA synthesis is increased considerably in the presence of NGF, these ganglia show only a very limited fiber outgrowth (Partlow and Larrabee, 1969; Partlow, 1969). Because the two major effects of NGF, stimulating RNA synthesis and causing substantial fiber outgrowth, can now be separated, it appears unlikely that NGF acts only on the transcriptional level.

A COMPARISON OF THE EFFECTS OF INSULIN AND NGF The separation of the effects of NGF on fiber outgrowth and on the maintenance or stimulation of metabolic activity is reminiscent of the effect of insulin on embryonic ganglia. Insulin, as does NGF, will preserve the normal histology and, therefore, presumably the metabolic activity, of eight-day sensory ganglia for at least one day in vitro (Levi-Montalcini, 1966). Insulin also parallels NGF in its effect on the conversion of glucose into CO2, lactate, and glutamate (Liuzzi et al., 1968) and on the stimulation of the incorporation of labeled acetate or mevalonic acid into such ganglia (Liuzzi and Foppen, 1968). Partlow (1969) has also observed that the time course of the incorporation of labeled uridine or amino acid into the 14-day-old sympathetic ganglia is similar with both NGF and insulin, these ganglia also being histologically well preserved by either agent. However, although insulin and NGF have these identical anabolic effects, they differ in their action in one significant respect. Insulin does not cause fiber outgrowth from either sensory (Levi-Montalcini, 1966) or sympathetic ganglia (Partlow, 1969). Thus, NGF might act like insulin to maintain the normal metabolic activity of the responsive neurons and, in addition, have the extra capability of stimulating fiber growth. It is pertinent to note that an anabolic effect of insulin is to stimulate the production of proteins already synthesized by an organism without the

FIGURE 6 Effects of actinomycin-D on fiber outgrowth and incorporation of labeled uridine into RNA of embryonic sympathetic ganglia with and without NGF. Fiber outgrowth was measured by the width of the halo. Incubation was for 15 hours (Partlow and Larrabee, 1969; Larrabee 1969).

requirement for prior RNA synthesis. It is known, for example, that insulin acts at the translational level to correct defects in the large ribosomal subunit from diabetic animals (Wool et al., 1968; Martin and Wool, 1968). Other hormones, such as growth hormone, act in a similar way, in this instance, to overcome a defect in the small ribosomal subunit from hypophysectomized animals (Korner, 1968; Barden and Korner, 1969). The long-term effects of these two hormones result in the synthesis of more ribosomes and endoplasmic reticulum (Wyatt and Tata, 1968), which is exactly the situation found for NGF-treated sensory ganglia (Levi-Montalcini et al., 1968).

Another growth factor has been isolated from the submaxillary gland, and progress has been made in determining its mechanism of action.

THE EPIDERMAL GROWTH FACTOR The EGF stimulates epidermal growth in intact animals or in tissue culture and concurrently stimulates incorporation into protein and all forms of cytoplasmic RNA (Cohen and Stastny, 1968). The initial cellular event induced by EGF that is responsible for this sequence of events appears to be a conversion of pre-

existing monomer ribosomes into polysomes. Because the EGF-induced polysome formation also occurs in the presence of cycloheximide or even a mixture of cycloheximide and puromycin, which inhibits protein synthesis more than 99 per cent, it is not dependent on the synthesis of new proteins. Nor, as the effect is obtained with cells preincubated in the absence of amino acids or glucose, does EGF appear to stimulate transport of these compounds. In addition, earlier work (Hoober and Cohen, 1967) also demonstrated that, in the presence of EGF, ribosomes from epidermis were twice as active as controls in an incorporation system using either endogenous mRNA or poly-U. In this respect, EGF action closely resembles the actions of insulin and growth hormone. Recent work indicates that EGF from the mouse submaxillary gland is a complex of 70,000 molecular weight composed of two different types of subunits (Taylor et al., 1970). One subunit has a molecular weight of 6,000, an isoionic point of 4.6, and carries the EGF activity. The other subunit is an esterase whose size (molecular weight 27,000), isoionic point (pH 5.6), and enzymatic specificity make it very similar to the γ subunit of 7S NGF. The EGF complex contains two subunits of each type.

A COMPARISON OF NGF AND PHYTOHEMAGGLUTININ There also exists another growth factor, phytohemagglutinin (PPHA), which as a protein shows some remarkable similarities to NGF, but whose mechanism of action apparently differs from that of EGF. PPHA, as isolated from red kidney beans, is a homogeneous glycoprotein of molecular weight 128,000 that may be reversibly dissociated in 8 M urea into about eight subunits of equal size but differing charge properties (Rigas et al., 1966). The parent protein has, as has NGF, two biological activities. One causes the agglutination of erythrocytes (Li and Osgood, 1949); the other, the induction of mitosis in normal human blood lymphocytes (Nowell, 1960). Rigas and Head (1969) have now shown that the two activities reside in different subunits. Although it has been reported that ³H-PPHA is taken up by the condensed heterochromatin of lymphocyte nuclei (Stanley et al., 1968), Kornfeld and Kornfeld (1970) have, in contrast, isolated from human erythrocyte membranes a glycopeptide which binds specifically to PPHA, abolishing both its agglutinating and mitosis-stimulating properties, and therefore having the properties of a membrane receptor site for PPHA. Correspondingly, a major part of the first RNA synthesized in response to PPHA is a heterogeneous form with high molecular weight, most of which remains in the nucleus and turns over fairly rapidly (Cooper, 1968; Darnell, 1968). Aronson and Wilt (1969) have suggested, on the basis of experiments with pregastrular sea-urchin embryos, that this RNA may be present and functioning as membrane-bound nuclear polysomes and also that the remaining nuclear RNA is a precursor to cytoplasmic RNA of the messenger type. In the PPHA-treated lymphocytes, the synthesis of the heterogeneous RNA species is rapidly overshadowed by the much greater synthesis of precursors for ribosomal RNA; the formation of ribosomes follows the pathways delineated in HeLa cells.

HORMONES AND GENE ACTIVITY If PPHA interacts with the nucleus, then it functions like a number of the steroid hormones. Aldosterone, which regulates sodium transport across epithelial cells, is firmly bound to a specific nuclear protein, and the complex appears to act as an inducer at the transcriptional level (Herman et al., 1968). Binding to the nuclear protein is highly specific, even stereospecific, because the biologically inactive isomer 17-isoaldosterone is not retained. The identity of this protein is not known, but there are at least two candidates-the histones and the acidic nuclear proteins. The latter show high rates of labeling when new RNA synthesis is intense (Church and McCarthy, 1967). The histones appear to be tissue and animal specific (Bustin and Cole, 1968) and to show a sequence asymmetry of the basic amino acids that might provide a DNA binding site (Bustin et al., 1969; DeLange et al., 1969; Bonner et al., 1969). Alternatively, histones may couple with chromosomal RNA, which itself is capable of hybridizing with homologous native DNA (Bekhor et al., 1969). It is now clear that the histone composition of a tissue responds to an altered physiology; when casein synthesis begins in the mammary gland, for example, the synthesis of two of the tissue-specific histories changes dramatically (Stellwagen and Cole, 1968; Hohmann and Cole, 1969).

Although it is not yet known if NGF acts at the transcriptional or translational level or by some entirely different mechanism, the information provided by the other model hormone systems may lead to further experimental clarification of the situation.

MODIFICATION BY SENSORY STIMULATION OR DURING LEARNING It has been reported that sustained afferent stimulation involving constant firing for many hours of an isolated stretch-receptor organ of the crayfish does not alter the amount of RNA present, although it does change the RNA base ratios during the first few hours (Grampp and Edström, 1963). Most other studies, however, indicate that stimulation of the cortex lowers the amount of both RNA and protein present (Geiger et al., 1956). In cortex slices, electrical stimulation decreases the rate of incorporation or precursors into RNA and protein, but kidney slices show no changes (Orrego, 1967; Orrego and Lipmann, 1967). Unilateral spreading cortical depression decreases ³H-leucine incorporation into soluble cortical protein of the depressed hemisphere, compared with that of the control hemisphere, although soluble brainstem protein from both sides had the same specific activity (Bennett and Edelman, 1969). Because the levels of many other metabolites also vary under these conditions, it seems likely that this and other phenomena noted above arise from alterations in precursor or energy pools rather than from direct effects on the protein synthetic machinery. On the other hand, there is good evidence that electroshock, which impairs memory consolidation, can disaggregate polysomes in the rabbit cortex (Vesco and Giuditta, 1968).

Although visual deprivation results in decreases in RNA and protein and also in their rates of synthesis in most cells of the optic system, the effects of light after a period of dark are stimulatory. Appel et al. (1967), for example, have reported significant increases in cortical polysomes and in the incorporation of radioactive leucine in adult rats exposed to light after three days in the dark. No change was noted in the level of total RNA, leucyl transfer RNA, or in activating enzymes.

Changes in the rates of RNA and protein synthesis occur when an animal undergoes training, but the question as to whether they are directly related to learning rather than to the other stimuli is difficult to answer (Glassman, 1969). The subject is discussed in detail by Hydén and Lange (this volume).

Acknowledgments

It is a pleasure to acknowledge that the work on the nerve growth factor described here was carried out in collaboration with Dr. Silvio Varon (Department of Biology, University of California at San Diego) and our colleagues Drs. Junichi Nomura, Andrew P. Smith, Lloyd A. Greene, and H. Ronald Fisk. The studies on the solubilization and examination of mouse brain membrane proteins are those of Drs. Robert M. Grossfeld and Thomas W. Waehneldt. The research was supported by a United States Public Health Service grant from the National Institute of Neurological Disease and Stroke, NB 04270, and by a grant from the National Science Foundation, GB 6878.

72 Mitochondria and Their Neurofunction

ALBERT L. LEHNINGER

SINCE THE LAST NRP Intensive Study Program, in 1966, some illuminating advances have been made in the study of cell organelles, particularly of mitochondria. These developments not only are relevant to the role of mitochondria in neuronal and glial cells, but they also may yield new insight into the evolutionary origin of organelles and into the nature of energy-transforming mechanisms in membranes. In the present paper two general areas are selected for special emphasis. The first includes the recently accumulated evidence that mitochondria possess a distinctive form of DNA as well as a distinctive apparatus for synthesis of protein. These new findings bring us squarely to the problem of the origin and biogenesis of organelles and their membranes, as well as the mechanism of non-Mendelian cytoplasmic inheritance. The second area concerns the molecular mechanisms by which energy transformations occur in the mitochondrial membrane, a question that has very broad implications for all energy-dependent, membrane-linked phenomena.

Mitochondrial DNA

That mitochondria undergo a division process after division of the cell is now strongly supported by isotopic experiments on *Neurospora* (Luck, 1963a, 1963b, 1965). In this organism, mitochondria do not arise *de novo*. They grow by accretion of precursors of small molecular weight, such as phospholipids and proteins, to pre-existing mitochondrial structure, and divide by formation of a septum and pinching-off, much as bacteria divide. This view has also been strongly supported by direct electron-microscope observations in liver and other tissues of higher species.

However, the most compelling and dramatic evidence for mitochondrial continuity has come from the discovery of mitochondrial DNA and the presence in mitochondria of the various molecular components required in the replication, transcription, and translation of DNA. Although evidence for the occurrence of DNA in mitochondria goes back more than 20 years, early observers considered it to be the result of nuclear contamination of mitochondrial fractions. In the last few years, however, with greatly improved methodology, mitochondria from more than 50 different types of cells have been found to possess a distinctive type of DNA; no mitochondria have yet been found that do not contain DNA.

Mitochondrial DNA (M-DNA) has been isolated and studied in detail (for review, see Nass, 1969) from a number of mammalian, avian, and amphibian tissues, from at least two higher plants, and from yeast and Neurospora. It is readily extracted and purified, although it represents only about 0.2 per cent of the total cell DNA in most somatic cells. In oocytes, however, it may represent up to 50 per cent of the total DNA. The buoyant density and, thus, the base composition of M-DNA are usually different from those of the nuclear DNA, and the two forms can therefore be separated readily and identified on density gradients. M-DNA has been examined in detail by both hydrodynamic and electron-microscope approaches. Its predominant form in nearly all types of mitochondria is open or twisted (supercoiled) circular duplexes with a contour length of about 4.5 to 5.5 μ and a mass of 9.0 to 10.0 \times 10⁶ daltons. An exception is the DNA of yeast mitochondria, which largely occurs in the form of linear molecules 4.0 to $4.5 \,\mu$ in

ALBERT L. LEHNINGER Department of Physiological Chemistry, The Johns Hopkins University School of Medicine, Baltimore, Maryland

length. Yeast M-DNA, however, has been found to possess complementary cohesive ends with the capacity to form hydrogen-bonded circles; presumably, it can be converted into covalent circles by action of DNA-ligase. Although the great bulk of mitochondrial DNA is found in the circular monomeric forms described above, small amounts of circular dimers, trimers, and tetramers have been found. particularly in mitochondria from HeLa cells, fibroblasts, and leucocytes from leukemia patients, in which they are often catenated or topologically linked (reviewed by Nass, 1969). Mitochondrial DNA does not hybridize with nuclear DNA of the same species, indicating that it has little similarity in base sequence. However, it does hybridize readily with mitochondrial RNA, indicating that the latter may be transcribed from mitochondrial DNA (Wood and Luck, 1969).

It has been estimated that each mitochondrion contains anywhere from two to six monomeric molecules of DNA. They are presumably identical and homogeneous, because the melting curve of M-DNA is very sharp and melted M-DNA reanneals very quickly, even at 0° C. Individual filaments of DNA are easily recognized in mitochondria of a number of higher cells (Nass et al., 1965; Nass and Nass, 1963a, 1963b).

Protein Synthesis in Mitochondria

For some time it has been known that isolated mitochondria are capable of incorporating amino acids into mitochondrial protein in vitro, but there have been a number of conflicting observations as to the characteristics of this process and its similarity to cytoplasmic protein synthesis in isolated ribosomes (reviewed by Slater et al., 1968; Roodyn and Wilkie, 1968). For example, it has been claimed that highenergy intermediates generated in electron transport are required for mitochondrial protein synthesis. However, more recent work indicates that ATP and GTP suffice as energy sources, although inhibitors of respiration and phosphorylation can profoundly modify mitochondrial protein synthesis (Wheeldon and Lehninger, 1966). There are other complications. Isolated mitochondria contain a substantial pool of endogenous amino acids, their membranes present permeability barriers to the entry of external amino acids, and they very likely contain specific amino acid carriers or transport mechanisms. Study of protein synthesis in intact mitochondria at present is therefore a little like studying protein synthesis in intact bacterial cells.

Despite these difficulties, it is now clear that isolated mitochondria contain all the familiar enzymatic apparatus for carrying out DNA-directed protein synthesis, including a distinctive DNA polymerase, different from that in the nucleus, and a distinctive DNA-directed, actinomycinsensitive RNA polymerase. Moreover, ribosomes, as well as ribosomal RNA, have been isolated from mitochondria. There has been some disagreement concerning the sedimentation coefficient of mitochondrial ribosomes, values between 73S and 81S having been reported (see Schmitt, 1969), but Küntzel (1969) has found what appears to be the basis of this variation. He has reported that the larger subunit of mitochondrial ribosomes is of the bacterial, or 50S, type, whereas the small subunit is of the type found in cytoplasm of eukaryotes, namely, 37S. Mitochondrial ribosomes contain the 16S and 23S species of rRNA characteristic of bacteria. Ribosomes have been visualized by the electron microscope in the matrix of *Neurospora* and in yeast mitochondria, in which they are rather closely associated with the inner membrane (Vignais et al., 1969).

Mitochondria have also been found to contain distinctive tRNAs and aminoacyl tRNA synthetases for various amino acids. In *Neurospora*, the mitochondria contain tRNAs that differ from homologous tRNAs in the cytoplasm, presumably in base composition and sequence, as they differ in buoyant density and can be separated by sedimentation methods (Barnett and Brown, 1967). Moreover, *Neurospora* mitochondria contain distinctive activating enzymes, which react readily with the corresponding mitochondrial tRNAs as aminoacyl acceptors, but do not react with the homologous cytoplasmic tRNAs (Barnett et al., 1967). Conversely, cytoplasmic activating enzymes do not react readily with mitochondrial tRNAs.

That mitochondrial protein synthesis is distinctively different from cytoplasmic protein synthesis is also shown by the observation that chloramphenicol, a characteristic inhibitor of bacterial protein synthesis, inhibits protein synthesis in mitochondria but not in the cytoplasm of eukaryotic cells (Kroon, 1965; Clark-Walker and Linnane, 1966). Conversely, cycloheximide, a characteristic inhibitor of protein synthesis in the 80S cytoplasmic ribosomes of eukaryotic cells, has no effect on mitochondrial protein synthesis. The similarity between mitochondrial and bacterial protein synthesis has been strikingly confirmed by the recent demonstration that the initiating amino acid in protein synthesis in mitochondria is N-formylmethionine (fMet), which is also the initiating amino acid in bacterial protein synthesis (Smith and Marcker, 1968). This observation contrasts with cytoplasmic protein synthesis, in which fMet has been excluded as the initiating amino acid. In many respects (Table I), the mitochondrial genetic apparatus closely resembles that of bacteria.

These recent advances have led to a number of interesting questions concerning the origin and biogenesis of mitochondria, the nature of the proteins synthesized by mitochondria, and the effect of mutation on mitochondrial function.

Evolutionary origin of mitochondria

The similarity between the bacterial and the mitochondrial systems for translation of genetic information has given strong support to the old concept that mitochondria may have had their evolutionary origin in bacteria that parasitized the cytoplasm of larger host cells, the precursors of present-day eukaryotes. This concept was already inherent in the visionary speculations of Altmann (1894). Mitochondria and bacteria have common denominators not only in their apparatus for protein synthesis, but also in their ultrastructure and enzyme distribution. Both bacteria and mitochondria possess an inner membrane of limited permeability and a sievelike outer wall or coat. The mesosomes of bacteria have their counterpart in the cristae of the mitochondria; both are infoldings of the inner membrane. Moreover, the enzymes of electron transport and oxidative phosphorylation are situated on the inner membrane in both bacteria and mitochondria.

In bacteria and mitochondria, the DNA is "bare" and is localized in nuclear zones or nucleoids. Because mitochondrial DNA is much smaller than that of bacteria, however, it appears possible that the primordial parasitizing bacteria lost many genes—presumably those that were redundant—during the course of evolution and development of eukaryotic cells.

Gene products of mitochondrial DNA

The nature of the proteins synthesized by mitochondria is a matter of some interest, as the relatively small DNA

TABLE I
Comparison of Basic Elements of Genetic Apparatus

	Prokaryote (E. coli)	Eukaryote (Neurospora)	
		Cytoplasm	Mitochondria
DNA	2×10^{9}	2×10^{9}	1×10^{7}
Ribosomes			
s20, w	70S	80S	~80S

sensitivity	+	0	+
Cycloheximide			
sensitivity	0	+	0

molecules in mitochondria are able to code for only about 40 polypeptide chains of 150 amino acid residues each. This figure must represent a maximum, because it has been shown that mitochondrial RNA hybridizes readily with mitochondrial DNA (Wood and Luck, 1969), which strongly suggests that a significant fraction of M-DNA codes for mitochondrial tRNAs and rRNAs.

Nearly all the amino acid incorporation by isolated mitochondria in vitro is into the proteins of the inner mitochondrial membrane, in a crude fraction called "structure protein." This fraction is now known to contain many polypeptide species, but only a very few of these become labeled in vitro in isolated mitochondria. To date, no evidence exists, from in vitro experiments, for incorporation of amino acids into any mitochondrial enzyme. Actually, it appears very likely that most mitochondrial proteins are coded by nuclear chromosomes. It is possible, however, that the mitochondrial genome may code for a few enzymes required by the "host" eukaryotic cell in some vital process. For example, two enzymes required in the biosynthesis of heme are localized in mitochondria, particularly ferrochelatase, which is found exclusively in the inner mitochondrial membrane (Schnaitman and Greenawalt, 1968). It is also possible that one or more of the polypeptide subunits of mitochondrial ribosomes are coded by the mitochondrial chromosome.

One of the most promising approaches to identification of the proteins specified by mitochondrial genes is the study of mutations in mitochondrial structure or function, which may be the result of changes in either the nuclear or mitochondrial chromosomes; a number of mutants defective in energy-coupling and ATP synthesis have been identified (Sherman and Slonimski, 1964; Mattoon and Sherman, 1966; Beck et al., 1968; Parker and Mattoon, 1969).

Recent work in our department (Hawley and Greenawalt, 1970) has shown that isolated *Neurospora* mitochondria tested in vitro show only a very small fraction of their in vivo activity, suggesting that protein synthesis in mitochondria is dependent upon as-yet-unidentified factor(s) contributed by the extramitochondrial cytoplasm or other intracellular structures. These are under examination.

The outer and inner mitochondrial membranes

Since the 1966 Intensive Study Program, several investigators have succeeded in separating the outer and inner membranes, a development made possible by the discovery of marker enzymes for the outer membrane, monoamine oxidase in particular, but also kynurenine hydroxylase and rotenone-insensitive cytochrome c reductase (Schnaitman and Greenawalt, 1968; Schnaitman, et al., 1967; Chan et al., 1970; Sottocasa et al., 1967a, 1967b). Such markers are essential for identification, because the outer membrane mass is usually only a small fraction of the inner membrane-about 10 per cent or less in liver mitochondria and as little as 2 per cent in heart. Direct analysis has shown that the outer membrane is richer in total lipids than the inner membrane and differs in lipid distribution (Stoffel and Schiefer, 1968). The inner membrane is remarkable in possessing only about 20 per cent lipid, of which a considerable fraction is cardiolipin, a lipid also present in large amounts in bacteria. The inner membrane is very thin (ca. 60 Å), although much of its mass is made up of the enzyme molecules involved in electron transport and oxidative phosphorylation. On the average, the inner membrane of mitochondria contains one assembly of respiratory carriers for each 40,000 Å², or a square 200 Å on each side, and from three to five of the elementary particles of Fernández-Morán, also called inner membrane spheres, which are now known to be adenosine triphosphate (ATP) synthetase molecules (Racker, 1967). The latter structures are visualized on the inner surface of the cristae after negative contrast procedures, but are not visible after osmium fixation. The spheres are about 80 to 90 Å in diameter in negative staining and the inner membrane is but 60 Å thick in osmium-fixed sections, so it has been suggested that the spheres do not normally protrude but may possess a flattened conformation in the intact membrane. Whether either of the mitochondrial membranes possesses a phospholipid bilayer core is not clear; however, the inner membrane does appear to have a continuous nonpolar phase.

Carrier systems in the mitochondrial membranes

Figure 1 shows the nature of the rather considerable metabolic traffic across the mitochondrial membranes in the intact cell. During normal mitochondrial function, fuels must pass from the cytoplasm into the inner compartment, in which oxidation and phosphorylation take place; accompanying this flow, adenosine diphosphate (ADP) and phosphate must also enter. Among the end-products leaving are ATP and HCO3-. The traffic across the mitochondrial membrane is remarkable in that most of the molecules that must cross it do not readily penetrate other biological membranes. For example, it is well known that the plasma membrane is completely impermeable to ATP and ADP, and is only very slowly permeable to citrate and phosphate, whereas these components cross the mitochondrial membrane readily in most cells. Actually, however, the mitochondrial membrane is also intrinsically impermeable to these ionic solutes, which are able to cross it only through the intervention of ion-specific carriers or transporters. A number of such specific carriers have recently been iden-

FIGURE 1 Metabolic exchanges across the mitochondrial membranes.

tified (Table II) (reviewed by Chappell, 1968). There are two distinctive types: fixed and mobile.

The ATP-ADP carrier is typical of the fixed carriers. It facilitates a stoichiometric exchange-diffusion process across the inner membrane, where one molecule of ADP going in is exchanged for one of ATP coming out; adenosine monophosphate (AMP) is not transported. No net transport of adenine nucleotide occurs—only exchange. The recognition of this carrier was made possible by the discovery of the toxic agent atractyloside, which blocks phosphorylation

 TABLE II

 Mitochondrial Membrane Transport Systems

Fixed carriers	Inhibitor
substrate(s)	
ADP-ATP	Atractyloside
Phosphate	Mersalyl
Ca ⁺⁺	Sr ⁺⁺
Malate	n-Butylmalonate
HCO3-	Diamox
Mobile carriers (shuttles) substrates	Carrier
Electron equivalents	Dihydroxyacetone
from NADH*	phosphate
Electron equivalents	
from NADPH**	Oxaloacetate
Fatty acids	Carnitine
Ion-carrying antibiotics	
K ⁺	Valinomycin, nonactin
Na ⁺	Gramicidin

** Reduced form of nicotinamide adenine dinucleotide phosphate.

of ADP by mitochondria, not through any intrinsic effect on the phosphorylation mechanism, but because it inhibits the transfer of ADP and ATP across the membrane. We have shown that atractyloside binds to the ADP-ATP carrier to "freeze" it-presumably by inducing a conformational change (Winkler and Lehninger, 1968)-in such a form that it can neither load nor unload ADP or ATP. Also among the fixed carriers are a phosphate carrier, amino acid carriers, and a bicarbonate carrier; the last appears to be carbonic anhydrase. Recently we have succeeded in extracting from the membrane in soluble form a specific Ca++binding protein of high affinity, which we had earlier concluded to be a specific Ca++ carrier (Reynafarje and Lehninger, 1969; Lehninger and Carafoli, 1969). The Ca++-binding protein is a relatively large molecule, over 100,000 in molecular weight. It also binds Sr++ and Mn++, but not Mg++.

The mobile carriers of rat-liver mitochondria include the well-known α -glycerophosphate carrier for electrons or reducing equivalents and the carnitine carrier for fatty acids (Tubbs and Garland, 1968). In the former, dihydroxyacetone phosphate accepts electrons and protons enzymatically; the resulting glycerol phosphate serves as a membranepermeant carrier. Carnitine serves as a lipid-soluble carrier of fatty acids, after enzymatic transfer of the fatty acyl group from fatty acyl CoA. Another type of mobile carrier is now of special interest, namely, the ion-carrying or ionophorous antibiotics (Pressman, 1970). More than 50 different antibiotics are now known which are capable of inducing permeability of mitochondria to alkali metal cations. The best known among these are gramicidin, valinomycin, nonactin, and nigericin; some are polypeptides and others are macrolides. Some of these antibiotics, such as gramicidin, induce permeability to all alkali metal cations and do not distinguish between Na⁺ and K⁺, whereas others, such as valinomycin, induce permeability to K⁺ but not Na⁺. Most of these antibiotics are annular molecules, with a relatively hydrophobic exterior and a highly polar "doughnut-hole." It has been postulated that such annular antibiotics may coordinate alkali metal cations within the polar doughnut hole. This hypothesis has been amply supported by recent work, particularly with nonactin. The crystalline K⁺ salt of this antibiotic has been subjected to X-ray analysis, which has shown the K+ to be coordinated within the annular ring (Kilbourn et al., 1967); nonactin does not form a complex with Na⁺. Valinomycin not only induces the capacity for K+ transport in mitochondria, but also transports K+ across artificial phospholipid bilayers and through nonbiological apolar phases, such as chloroform (reviewed by Mueller and Rudin, 1969).

Although the ionophorous antibiotics are toxic agents elaborated by microorganisms, it appears possible that they may serve as instructive molecular prototypes of K⁺ or Na⁺ gates in excitable membranes. Mueller and Rudin (1968) have shown that the antibiotic alamethicin will confer on synthetic phospholipid bilayers the property of electrical excitability, providing a K⁺ gradient is imposed. Evidently alamethicin allows K⁺ to pass only when the system is electrically perturbed. The uncoupling agent 2, 4-dinitrophenol also can act as a mobile transmembrane carrier, specifically of H⁺ ions (Hopfer et al., 1968). The intrinsic impermeability of the inner mitochondrial membrane to H⁺, Na⁺, and K⁺, and the increase in permeability induced by agents such as valinomycin and 2, 4-dinitrophenol, are important elements in the transformation of electron transport energy (see below).

Modalities of energy coupling in mitochondria

We still have very little information as to the molecular mechanism by which ATP is regenerated from ADP and phosphate during electron transport in mitochondria. Although it had appeared for some years that the solution to this problem was just around the corner, more recently a theoretical and experimental trilemma has developed. There are currently three major hypotheses for the mechanism of oxidative phosphorylation: the chemical coupling hypothesis; the chemiosmotic coupling hypothesis; and the conformational coupling hypothesis. These hypotheses are by no means of parochial interest to "mitochondriacs" only, because they are relevant to the action of all types of membranes that form or utilize ATP. It must be recalled that phosphorylation of ADP coupled with electron transport is a fundamental process not only in respiration in mitochondria, but also in photosynthetic phosphorylation of chloroplasts and in respiration in prokaryotic bacteria, in which the properties of the membrane-linked, energyconserving mechanisms appear to be very similar. Moreover, they are also relevant to the action of the Na+-transporting adenosine triphosphatase systems of plasma membranes, which show many similarities to the H+-transporting adenosine triphosphatase system of the mitochondrial membrane.

The free energy of electron transport in mitochondria can be utilized not only to cause coupled synthesis of ATP from ADP and phosphate, but also can be used to drive at least two other types of energy-requiring processes—ion transport and conformational and/or volume changes (reviewed by Lehninger, 1964). For some time it has been known that mitochondria can accumulate certain cations, such as Ca⁺⁺ and K⁺ (in the presence of valinomycin), from the suspending medium at the expense of electron transport, in a process that is stoichiometric with electron transport but alternative to oxidative phosphorylation. Such ion movements are uncoupled by 2, 4-dinitrophenol, as is oxidative phosphorylation of ADP. During cation accumulation in mitochondria, there is a simultaneous energylinked extrusion of H^+ into the medium. Proton ejection (or its equivalent hydroxyl ion accumulation) is currently regarded as the primary event to which is coupled the accumulation of external cations such as Ca⁺⁺ and K⁺.

The other modality of energy coupling is less well known in molecular terms, but is conspicuous ultrastructurally. Mitochondria undergo two types of energy-dependent conformational change (Lehninger, 1964). The first is a relatively slow, "large-amplitude," swelling-contraction cycle, in which the mitochondria undergo large increases and decreases in volume; not all mitochondria show this property. The second is a very rapid, "small-amplitude" change, in which the total mitochondrial volume does not change but in which an internal rearrangement of mitochondrial structure takes place. This type of structural change, which takes place in all mitochondria, is characteristically influenced by respiratory inhibitors and uncoupling agents. These three modalities of energy coupling, i.e., phosphorylation of ADP, active ion transport, and conformational changes, are the basic processes on which the three current hypotheses of mitochondrial energy coupling are constructed (Figure 2).

The chemical coupling hypothesis

This hypothesis proposes that electron transport generates a high-energy chemical intermediate, often symbolized $X \sim I$, which is the energetic precursor of the high-energy phosphate bond in ATP, in a sequence of linked reactions that have common high-energy intermediates. One variant of the chemical coupling hypothesis is shown in Figure 3. The hypothesis has been the working assumption of most investigators since it was first postulated in 1953–1954 (see Lehninger, 1964). It is similar in principle to the commonintermediate reaction schemes of most multienzyme systems, in particular that of the ATP-yielding glycolytic cycle. This hypothesis thus has ample biochemical precedent. The chemical coupling hypothesis can also be made to account for mitochondrial H⁺ transport, if it is assumed that the postulated high-energy intermediate $X \sim I$ can undergo asymmetric hydrolysis across the membrane by the action of a vectorial enzyme:

$$H^+_{inside} + OH^-_{outside} + X \sim I \rightarrow X-OH + H-I.$$

Such a reaction would leave the outer compartment more acid and the inner more alkaline. The chemical intermediate $X \sim I$ can also account for swelling-contraction cycles, if $X \sim I$ breakdown or discharge is accompanied by a conformational change transmitted to the membrane. In fact, the chemical coupling hypothesis is capable of explaining nearly all existing experimental observations on mitochondrial energy coupling (see Greville, 1969).

However, the hypothesis has two conspicuous flaws. First, there is at present no significant evidence for the formation or existence of the imputed high-energy chemical intermediates, after many years of effort devoted to finding them. Second, the chemical coupling hypothesis does not account for the widely confirmed observation that the mitochondrial membrane is essential for oxidative phosphorylation, and must be present as an enclosed vesicle. Actually, the chemical coupling hypothesis provides no role for the membrane other than as "floor space" for the respiratory assemblies. It is, of course, still possible that the imputed high-energy chemical intermediates may yet be found and that someone will succeed in reconstructing

FIGURE 2 Energy-coupling hypotheses.

FIGURE 3 A chemical coupling hypothesis.

oxidative phosphorylation in a membrane-independent system, but the probability appears rather low.

The chemiosmotic hypothesis

The chemiosmotic hypothesis, which has earlier forerunners, was explicitly postulated in 1961 by Mitchell in a rudimentary form and later developed in a much more detailed manner (Greville, 1969; Mitchell, 1961, 1966, 1968). It is perhaps more accurately termed the electrochemical or protontranslocation hypothesis. The chemiosmotic hypothesis (Figure 4) proposes that the membrane is an essential element in energy coupling, across which a proton gradient or "proton-motive" force is generated by electron transport via the membrane-linked carriers. Because the mitochondrial membrane is postulated to be impermeable to protons, the proton gradient generated by electron transport thus constitutes a high-energy state. The proton-motive force so generated is then used to drive the dehydrating synthesis of ATP from ADP and phosphate through the action of an asymmetric or vectorial adenosine triphosphatase, also situated in the membrane, which is capable of removing the elements of H₂O from ADP and phosphate to form ATP, in such a way that H⁺ enters the inside compartment and the OH⁻ the outer compartment. The proton-motive force generated by electron transport thus "pulls" the synthesis of ATP from ADP and phosphate; the result is a cyclic proton current across the membrane, outwardly directed by electron transport and inwardly directed by ATP formation. In more recent refinements of the chemiosmotic hypothesis, Mitchell has proposed that there need

FIGURE 4 The chemiosmotic hypothesis.

not be a large proton gradient across the membrane if a transmembrane potential difference that is energetically equivalent is generated by electron transport (Mitchell and Moyle, 1969).

An interesting feature of the chemiosmotic hypothesis is the prediction that uncoupling agents act by virtue of their capacity to serve as lipid-soluble proton carriers that make the lipid-phase of the membrane permeable to protons, thus short-circuiting the proton current. It was further postulated that the electrochemical gradient generated by electron transport is the ultimate driving force for other mitochondrial ion-transport processes and that it also is responsible for conformational changes in membranes.

A number of features of the chemiosmotic hypothesis have been given direct experimental support. There is good evidence for the postulated impermeability of the mitochondrial membrane to H^+ ions, although there are those who choose to interpret existing data otherwise. The capacity of the respiratory chain to pump protons outward is particularly well established; moreover, studies on the stoichiometry of proton transport indicate that two H^+ are ejected per pair of electrons per site (see Greville, 1969). That ATP synthesis and hydrolysis are also accompanied by proton uptake and ejection, respectively, has also been established; there is a molar stoichiometry of about three H+/ATP at pH 7.0 (Bielawski and Lehninger, 1966). The mitochondrial membrane enzyme systems therefore have the predicted sidedness in relation to one another and also the minimum required stoichiometry. Moreover, there is considerable evidence that 2, 4-dinitrophenol increases the permeability of mitochondria to H⁺ (Greville, 1969). In fact, 2, 4-dinitrophenol added to synthetic phospholipid bilayers not only increases the permeability to H+ dramatically (Bielawski et al., 1966), but this effect is specific for H⁺; a synthetic phospholipid bilayer in the presence of 2, 4dinitrophenol comes very close to giving a theoretical membrane potential of 59 millivolts for a gradient of 1.0 pH unit at 25° C (Hopfer et al., 1968). One of the most interesting pieces of evidence supporting the chemiosmotic hypothesis is Jagendorf's finding that an artificially created pH gradient across the chloroplast membrane in the dark causes ATP to be formed from ADP and phosphate (Jagendorf, 1967).

The chemiosmotic hypothesis has been vigorously opposed, particularly by Chance and by Slater. Chance and his colleagues failed to observe a significant change in the intramitochondrial or intracristal pH measured with an adsorbed pH indicator (bromothymol blue) in the transition from resting (State 4) to active (State 3) respiration induced by adding ADP. However, their interpretations of this evidence have been criticized. There is probably no necessity to expect a large change in transmembrane pH in a tightly coupled system under steady state conditions. In interesting recent experiments in which the transmembrane potential across the membrane of large mitochondira has been measured directly with an electrode inserted into the matrix, no evidence of a substantial potential difference was found (Tupper and Tedeschi, 1969). There are still many technical difficulties in experimental procedures designed to test the occurrence of chemical or electrical gradients across the mitochondrial membrane, and it is perhaps wisest at the moment not to accept all such data at face value.

At the moment, the chemiosmotic hypothesis is unfashionable in some quarters, but, on any objective grounds, it cannot be dismissed from the most serious consideration. Moreover, it appears to account particularly well for energy coupling in chloroplasts.

The conformational-coupling hypothesis

That conformational changes of the electron carrier molecules may be involved in the transformation of respiration energy was first suggested in 1961, to account for the mechanism of respiration-linked swelling-contraction cycles of mitochondria (Lehninger, 1960, 1961, 1964). Conformational changes were later invoked more explicitly as a vehicle of energy coupling by Boyer (1968). Not until recently, however, did a firmer experimental basis for this

concept arise, particularly from electron-microscope investigations of Hackenbrock (1966, 1968; Hackenbrock and Gamble, in press) on mitochondria sampled in various stages of the respiratory cycle. Mitochondria respiring in State 4 (the resting state; no ADP) show the classical or "orthodox" conformation of the cristae and inner matrix. On the addition of ADP, which stimulates respiration to yield State 3, the mitochondria quickly (within one second) undergo transformation to the "condensed" conformation, in which the inner compartment becomes contracted to about 50 per cent of its State-4 volume and the inner membrane becomes contorted and shrunken. When all the added ADP is phosphorylated, the mitochondria return to the orthodox conformation. There is no over-all volume change of the mitochondria; only the inner membrane undergoes such rapidly reversible changes in conformation. These changes are characteristically inhibited (or promoted) by inhibitors of respiration and phosphorylation. Similar observations have been made more recently on other types of mitochondria in Green's laboratory (Penniston et al., 1968).

One possible interpretation of the inner compartment changes is that they are merely passive and secondary to respiration-dependent ion movements and are thus the result of changes in internal osmolar concentration. It has recently been shown, however, that the total osmolarity of the inner compartment of the mitochondria does not change during State 4 to State 3 transitions. Hackenbrock has therefore postulated that the respiration-linked conformational changes in the inner membrane represent the vehicle by which the energy of electron transport is converted into the phosphate-bond energy of ATP. Conformational coupling has also been vigorously championed by Green and his colleagues (Penniston et al., 1968).

The conformational-coupling hypothesis has also been given strong support in recent work of Chance and his colleagues, who have used the fluorescent dye 1-anilino-8naphthalenesulfonic acid (ANS) as a probe of changes in mitochondrial structure during respiratory transitions (Azzi et al., 1969). ANS bound to mitochondria undergoes extremely rapid changes in fluorescence during respiratory transitions, which Chance has interpreted as reflecting energy-dependent conformational changes in membrane proteins. Such fluorescence changes may also be caused by changes in the dielectric properties of the medium or the surface to which it is bound, or in the degree or manner of binding. It is especially noteworthy that the fluorescence changes are extremely rapid; in fact, they appear to be the earliest physical or chemical changes yet observed during respiratory transitions and thus may be closely associated with the primary act of energy transformation.

Despite the considerable recent attention given the conformational-coupling hypothesis, specific molecular formulations have not been described, probably because there are some thermodynamic, kinetic, and geometric restrictions on possible mechanisms (Williams, 1969). The model in Figure 5 may be proposed to yield at least a schematic idea of one possible mechanism. It assumes that the electroncarrier molecules have different conformations in their oxidized and reduced states; this has in fact been established for cytochrome c. Similarly, it is assumed that the ATP synthetase molecule may also exist in a taut or energized form, in which ATP formation readily takes place, and in a relaxed or energy-poor form, which is inactive. When ADP becomes available to any given respiratory assembly, the carriers will become oxidized and thus undergo transition into their energized forms. It is then suggested that this all-or-none conformational transition is to be transmitted sterically or mechanically to the ATP synthetase molecule, either directly or via membrane structure proteins, through cooperative interactions of the membrane protomers. The ATP synthetase is thus converted into its active or taut form, causing it to make ATP. In this way a conformational change in the carriers may be converted into the chemical change of ATP formation (Figure 6, page 838).

It must be pointed out that this hypothesis requires that any given respiratory assembly undergoes all-or-none transitions between two steady states (States 4 and 3), and that energy recovery is associated with the transition of the assembly rather than with the steady state itself. Because each mitochondrion has many thousands of such assemblies, the transitions may average out over time to account for the observed linearity of ATP formation with electron transport. In the light of present knowledge of protein conformational transitions, conformational-coupling hypotheses must necessarily have such an on-off character. It is otherwise very difficult, if not actually impossible, to construct a conformational-coupling mechanism that can function in one continuous steady state. It is interesting that such a mechanism puts respiratory energy conversion into the same class of mechanochemical or chemomechanical processes as those taking place in actomyosin, in ribosomes, in microtubules, and in flagella.

At present it is not possible to choose among these hypotheses; airtight experiments capable of destroying one or the other have proved to be very difficult to design. Whatever the molecular basis for the energy-coupling process, it now appears highly probable that the same basic mechanism will prove to operate in mitochondria, in chloroplasts, in bacterial membranes, and may be directly relevant to the ATP-dependent electrogenic pumps of the plasma membrane.

Mitochondria in neurofunction

Brain mitochondria are extremely active in protein synthesis, and exceed mitochondria from liver and certain other organs in this activity. Work in our laboratory (Hamberger et al., 1970) has shown that mitochondria isolated from neuronal cells are considerably more active in protein synthesis than mitochondria from glial cells. Protein synthesis in mitochondria isolated from whole rabbit brain is dramatically stimulated if the rabbits are first forced to swim in a tank of water for 30 to 40 minutes (Hamberger et al., 1969). Whether this increase is due to a systemic effect of muscular activity or to psychic activity is not clear. The possible role of mitochondria in the synthesis of enzymes at nerve endings, particularly enzymes concerned in the secretion and metabolism of neurotransmitter substances, deserves further study.

The extraordinary affinity and capacity of most mitochondria, including those of the brain, to segregate Ca^{++} during respiration (Lehninger et al., 1967) have suggested that mitochondria may play a role in excitation-contraction coupling and in recovery. Recent investigations have revealed that mitochondria rather than sarcoplasmic reticulum may be the major Ca^{++} -segregating organelle in some types of muscle, particularly "red" muscles, which are rich in mitochondria; similarly, mitochondria may play a role in sequestration and release of Ca^{2+} at nerve endings.

It has been pointed out that the mitochondrial membrane may be a useful model of the excitable neuronal membrane (Lehninger, 1968), particularly with respect to the interplay between Ca^{2+} and Na^+ or K^+ , which is now considered to be a central process in the transmission of impulses along the axon. For one thing, the molecular basis for passage of monovalent cations across membranes can be approached through study of the characteristic action of valinomycin and other ionophorous antibiotics on mitochondrial membranes.

It has often been suggested that the neuronal membrane is normally poised in a metastable state that responds in an all-or-none manner to triggering impulses, leading to movements of Ca²⁺ and Na⁺. Like the neuronal membrane, the mitochondrial membrane also possesses specific binding sites for Ca++ and also interacts with monovalent cations (Lehninger, 1968). Under certain conditions of pH and K+ concentration, rat-liver mitochondria will respond to additions of Ca++ (the stimulus) in a manner suggesting that they are poised in a metastable state, i.e., they rapidly take up Ca++ and eject H+ and then proceed to reverse and overshoot, to produce a highly damped oscillation resembling a slow-motion action potential (Carafoli et al., 1966). Chemical exchanges across the mitochondrial membrane can now be measured with great sensitivity and ease, and much of the basic enzymology of mitochondria is understood. The recent success of Tupper and Tedeschi (1969) in inserting electrodes into mitochondria should now make it possible to measure electrical activity of mitochondrial membranes, and thus to supplement the extensive biochemical information.

Although it may be stretching facts to compare the inner

FIGURE 5A The conformational states of mouse-liver mitochondria. The orthodox conformation (in the absence of ADP).

mitochondrial membrane with the neuronal membrane, such similarities should not be dismissed lightly, as they may yield new insights. Some day we must come closer to a unifying theory of membrane structure and function, and it may be that the easily accessible mitochondrial membranes will yield important clues to the function and behavior of the neuronal membrane.

73 Neuronal Dynamics and Neuroplasmic Flow

PAUL A. WEISS

IN RECENT DECADES, interest in the dynamics of the neuron has been enlivened by the realization that nerve fibers are not static; that they are more than "live wires" spun out once and for all during development for service to the finished body as carriers for the propagation and transmission of impulses. In the older static-structural image, the neuron was tacitly denied some of the essential features of what in those days was referred to as "protoplasm." The neuron was conceded some limited power of respiratory metabolism as fuel for "conductivity," but was denied the powers of contractility and, above all, of postnatal growth; for growth was measured in terms of cell enlargement or cell multiplication, neither of which was observed in mature neurons of higher vertebrates, except in post-traumatic regeneration. The very fact that regeneration was considered to be a reawakening from dormancy, rather than simply the intensified expression of a continuously ongoing growth process, as which it now has been recognized, is telling testimony of the change of view that has occurred.

This change, which conceded to the mature neuron the properties of growth and contractility, thus readmitting it to the ranks of full-fledged living cells, has come about by the confluence of two streams of facts and inferences. One stream has been the dramatic progress of molecular biology in resolving "protoplasm" into rather well-defined populations of specific macromolecules and more ubiquitous smaller molecules and ions, and especially in the detailed identification of the processes of "protoplasmic contractility" and "protoplasmic reproduction" in molecular terms. The other contributing stream was the demonstration of the phenomenon of axonal flow or, more broadly, "neuroplasmic flow." While the nucleated soma of the neuron has been conclusively shown to be the major production plant for the specific macromolecular systems needed in the neuronal household, the studies on axonal flow have revealed the facts and modes of traffic from the localized production centers to sites of consumption and distant destinations.

As my presentation will indicate, there is distinct "hybrid vigor" to be expected from the continued blending of these two lines of investigation, for, as in an industrial operation, the managerial considerations of the production process cannot be separated from those of the distribution and marketing. Biochemical research on the neuron has focused

PAULA. WEISS The Rockefeller University, New York

predominantly on the former, that is, on the synthesis of specific compounds from raw materials, which is the task of a chemical industry. Yet, a cell can more aptly be compared to an industry that shapes its diverse chemical materials into such ordered structures as machines or buildings or pipelines. This aspect of the cell as an industry of structural devices has only lately come into prominence.

Turning to what, in the nerve fibers, corresponds to the distribution and marketing problems of an industry, there are, first, the economical considerations of how much of a given product is manufactured in the factory, how much is stored, how much is shipped out, where it ends, how long it lasts, and if and how demand controls production and shipping schedules. Second, there are the *technological* aspects of distribution, i.e., the means by which the transport from source to destination is carried out and regulated. We know that in the neuron this is effected by axonal flow, but unfortunately, with the exception of transport of ions and relatively small molecules across membranes and the ingestion of matter in phagocytosis and pinocytosis, our knowledge of the mechanism of cellular transport is dismally poor. This lack of proper models accounts for the striking disproportion in the amount of attention given to the economics of the translocation of neuronal material, as against its technological problems, as is well illustrated by such technologically naive terms as "migratory protein," as if the molecule had legs with which to "migrate."

We evidently are just at the beginning of realizing, identifying, and disentangling the complex web of intimately interrelated processes that operate in the industrial system of the neuron. In this rudimentary state of knowledge, it seems far more important to gather further information with care and accuracy and to correlate the data from the diverse technical approaches involved, such as microanatomy and submicroanatomy, cytochemistry, cinemicrography, hydrodynamics, pharmacology, and so forth, than to indulge in sweeping generalizations, or even to give an air of finality to reasonably validated ones that are subject to further verification. It is my aim to let the following discussion reflect this cautionary attitude.

Neuronal cell dynamics

Much detailed information on neuroplasmic synthesis will be given in subsequent chapters. Detailed accounts of axoplasmic flow have been given in several recent reviews (Barondes, 1969; Lubińska, 1964; Weiss, 1963, 1967a, 1969a). To avoid repetition, I shall confine myself to sketching the emergence of an integrated and unified concep: of neuronal dynamics from the variegated collection of data.

PROTEIN SYNTHESIS Using the rate of protein synthesis as indicator of the intensity of the renewal of the macromolecular population, the mature nerve cell must be rated as close to the most active of all cell types, which include intestinal mucosa, bone marrow, or certain tumor cells. The use of the term "protein" in the singular, disregarding the great diversity of protein species, is but a tactical convenience. The transfer of "genetic information" to a cellular feature is safely established through the standard formula of transcription of nucleic-acid pair sequences from DNA to RNA, followed by translations of messenger RNA series into conforming seriations of amino acids to yield polypeptides, which then combine to proteins in various conformations from linear to three-dimensional patterns. From this point on, the safe track of information is lost. The continuation of chemical differentiation as the result of enzyme activity and of compounding new products in bulk, that is, in purely scalar terms, can still be extrapolated from the same model, but the physical order restraining the chemical interactions in the cell in coordinated fashion calls for the introduction (often no more than an invocation) of organizing principles generally lumped under the term "control," the nature of which is not only quite obscure but often not even properly recognized, let alone critically investigated.

DIFFERENTIATION VS. PROLIFERATION The whole problem of "differentiation" is in this indefinite state. I am not talking here about the various ingenious attempts to explain the differential changes in the bulk composition of a given cell by "gene repression" and "de-repression" which have been derived from the study of prokaryotes. The generative and the somatic cell are one and the same in these simple forms, so they can offer no model for cell differentiation in the higher metazoans, whose many disparately differentiated cell types, once they have acquired special properties, can keep on multiplying almost indefinitely, each true to its own differentially specialized cell type even in an indifferent environment, and even though all of them continue to carry the same common genome (Defendi, 1964; Ursprung, 1968; Weiss, 1953). Neither the manner in which this relative stability of self perpetuation is insured, nor the range within which it can be modified, are understood; the only well-attested facts are the undiluted propagation of specificity in the offspring of an established cell line and the limited degrees of transformability of the strain.

This state of uncertainty reflects directly on a prominent

feature of the mature nerve cell, namely, the absence of neuronal cell multiplication. At definite times, varying for different parts of the nervous system, neuronal cell division ceases in vertebrates in postmetamorphic (or, in the higher forms, in perinatal) stages. Now, in most proliferating tissues, a given cell has the dual capacity of directing its synthetic machinery either toward the production of another cell of the same type, or toward manufacturing specialized cell products (Weiss, 1969b). The decision between these alternatives is made either by conditions in the microenvironment of the cell or by an internal time clock indigenous to the particular cell strain. The question is what switches the neuronal machinery from proliferation into production.

Proliferation stops when DNA replication in the nucleus ceases, which can be determined by the cessation of the incorporation of thymidine. Mature brain neurons no longer incorporate thymidine.* However, Gurdon (1967) has shown in a most striking experiment that the nucleus of such a nonproliferating neuron of an adult frog can again be made to start incorporating thymidine massively if it is excised and transplanted into the cytoplasm of an enucleated egg. Capacity for DNA replication, therefore, is ever present in the neuronal nucleus, but is actively suppressed by the nuclear environment (Jacobson, 1968). In my own experience with many thousands of amphibian central nervous systems, I remember having seen only two instances of mitotic figures in mature neurons with fully developed axons and neurofibrils; in both cases they were in ectopic position in the central canal. Perhaps the capacity of cerebrospinal fluid to unblock DNA stasis in mature neurons might be worth testing.

At any rate, the absence of DNA replication restricts the observed high rate of protein synthesis to the role of maintaining the existing cellular unit and to producing specific products assigned to that cell type, which, in the present case, include "neurohumors" and "neurosecretions" of the older literature as well as the enzyme systems instrumental in their manufacture. However, while in most other terminal cells of the mature organism the internal catabolic degradation of the macromolecules is spatially so closely intermingled with their replenishment by neosynthesis that bulk determinations reveal only the balance sheet of the account, the sharp localization of the production site in the neuron makes the latter into a natural separator between the two phases.

NUCLEAR PRIMACY The cell dynamics of the neuron brings to mind that of another cell that also has an eccentrically located nucleus, namely, the alga *Acetabularia* (Brachet, 1965). The nucleus in this single-celled alga lies at

^{*} Sporadic residual straggler neurons have been reported, however, by Altman (1967).

the end of a long stalk, the other end of which forms characteristic structures roughly comparable to nerve endings. When such an alga is enucleated by amputation of the lower nucleated end, it can survive and even regenerate ablated tops, although its viability declines as does also the rate of residual protein synthesis in the enucleated fragment. At any rate, the fact that protein is still synthesized for some time in the absence of the nucleus is noteworthy. A more detailed analysis of this synthetic process, however, has reduced its comparability to the neuron by showing that autonomous DNA-containing chloroplasts in the enucleate fragments permit the continuation of RNA synthesis. This, in turn, actuates continued protein synthesis, as evidenced by the active incorporation of isotopically labeled amino acids into isolated chloroplasts comparable to such other cell organelles as mitochondria (Reich and Luck, 1966) and basal bodies of cilia (Randall et al., 1967), which have their own DNA machinery.

By contrast, the axon offers a much clearer and cleaner demarcation from the nucleated soma. The only DNAequipped organelles in axoplasm, the mitochondria, assume less than one per cent of the axonal volume. The main axonal mass from the axon hillock down is free of ribosomes, and although low amounts of RNA not attributable to contaminations have been reported to be present in a few types of nerve fibers (Edström, 1969), evidence of active protein synthesis along the course of the axon (Singer, 1968) has generally been questioned (Droz, 1969). The burden of protein synthesis in the neuron thus rests conclusively upon the soma. This primacy of the nucleated territory does not necessarily imply exclusivity, and the synthesis of some proteins at nerve endings has been asserted (Austin and Morgan, 1967). In this connection, one must also consider that, daily, each nerve ending receives hundreds of mitochondria through the axonal flow. These then break down, raising the question of whether, perhaps, the resulting release of mitochondrial DNA and RNA might not be instrumental in the reported protein synthesis at nerve terminals (see below).

AXONAL FLOW AS DRAINAGE When axonal flow was first demonstrated, all that was certain was that substance leaves the cell body at a rate that advances the cylindrical column of the axon from one to a few millimeters daily (Weiss and Hiscoe, 1948). Fate, function, and composition of the flow were at first wholly conjectural. It was sheer assumption when I suggested, in contradiction to Ramón y Cajal, that the axon itself cannot synthesize the replacements for that population of its macromolecules that is subject to continual catabolic degradation, and that axonal flow therefore represents a system in stationary balance between its own self-consumption and its replenishment from the manufacturing center located in the cell soma. Enzymes and other proteins suggested themselves as the most indicative markers for measuring the flowing contingent. The high ammonia liberation from nerve, recorded in the older literature, could then be regarded as an index of protein de-amination. A calculation based on this tenuous argument yielded an average nerve protein half-life of a few weeks, which corresponds to the more direct and accurate later determinations (Lajtha, 1964) of protein turnover in brain. Calculating further, from this short life expectancy, the rate at which a supply stream would have to compensate for the continual depletion to maintain a steady state, we calculated an advance of the feeder column at an average daily rate of one millimeter (Weiss and Hiscoe, 1948). The identity of this value with the observed rate of the axonal flow was suggestive, but not conclusive, evidence for our interpretation of axonal flow and of its premises. The clinching proof came only from the study of translocations of isotopically marked protein.

Before turning to them, let me mention a few points on method. Bulk measurements are particularly uninformative when one deals with inhomogeneous sources-for instance, mixtures of nerve cell bodies, nerve fibers, glia cells, and vascular tissue, such as are being used in metabolic assays of slices or homogenates of central or peripheral nerve tissue. The delicate micro-techniques of separating pure neuronal cell bodies from their associated glial cells (Hydén, 1967) and of extruding pure axonal core from the enveloping myelin and Schwann cell (Edström, 1964; Koenig, 1965) promise to circumvent this difficulty, provided the trauma involved and the microscopically indistinct residual contaminants prove to be negligible. Some of these difficulties can be bypassed by comparing intact peripheral nerve with nerves transformed into cords of Schwann cells as a result of earlier transection (see below).

A further cautionary note pertains to the frequent treatment of protein as if it were in free soluble form. While identifiable microscopic and submicroscopic aggregates of structural proteins are clearly recognizable, systems devoid of such conspicuous criteria are still rather elusive, and the empirical division, after extraction, into soluble and insoluble proteins can hardly represent the graded scale of complex formations. This consideration has a crucial bearing on our understanding of the cohesiveness of the substance flow from the cell body. Sufficient evidence has been accumulated by now to prove conclusively that the one-millimeter type of axonal flow consists of flow of the whole axon as a structurally cohesive semisolid system, rather than as substance flow within an axon that is consolidated in a fixed position. There is also considerable evidence for liquid transport channels within the cohesive axonal matrix, but this is a second system sui generis, which must not be confounded with the moving reference system within which it lies enclosed. Until we have more concrete information about

the structural properties of the axoplasmic matrix beyond what is implied in the general term of "thixotropic gel," we cannot take it for granted that "nonstructural" proteins are necessarily freely mobile. Just as an isotope-labeled amino acid serves as a marker for the protein in which it is incorporated, so it may be necessary to consider the protein prima facie as a marker for a larger substance continuum with which it is physically and chemically linked.

As in the coacervation of gels in general, this aspect immediately raises the question of *water* as a structural component of the neuronal matrix. I know of no data on how much of the approximately 85 per cent water content of the neuron is freely exchangeable, how much is chemically bound to hydrated compounds, and how much is physically enmeshed in the tangled structure of the large macromolecules. Preliminary explorations in my laboratory (Kreutzberg, unpublished) have shown that tritiated water, locally applied to the soma of spinal-ganglion cells, gradually appears in significant proportions in the peripheral axons of the spinal nerves issuing from those cells; it is distinguishable from water exchanged peripherally across the axonal surface. Systematic explorations of this problem on a broader scale are urgently needed.

Analysis by radioisotopes

We can now take up briefly the rather spectacular advances made in tracking protein down the axon by isotope labeling. The early experiments using ³²P and ¹⁴C as markers did not go much beyond confirming the phenomenon of axonal flow and, in some cases, its average velocity of one mm per day (Weiss, 1961b). A major step forward came only with the introduction of tritiated molecules as tracers by Droz and Leblond (1963). Amino acids as protein markers have been applied (1) by single-pulse injections into an animal; (2) by regional injections (Ochs et al., 1962; Miani, 1964); (3) by strictly localized application to the cell bodies of origin of the test neurons (Taylor and Weiss, 1965; Weiss and Holland, 1967; McEwen and Grafstein, 1968; Rahmann, 1968); and (4) by explanting neurons into the labeling solution (Weiss, 1967b). The following paragraph summarizes results with (1) by Droz (1969).

A few minutes after intravenous injection of tritiated leucine in the rat, radioactivity is detectable in the nucleus of the neuronal soma. The evidence seems adequate that its source is protein-incorporated, rather than free, amino acid. Sampling at graded intervals after injection reveals the sequential spreading of the labeled protein from the nucleolus to the rest of the nucleus, and from there to the perikaryon. After two to five minutes, the concentration of labeled protein has become highest in the RNA-rich Nissl substance, reaching a peak in the Golgi body at about half an hour, and reaching the smooth reticulo-endothelium a few hours later, where some of it may remain for days. Some of the protein, however, bypasses the complex cytoplasmic machinery and moves directly from the nucleus into the axon, at the base of which the first traces of the label appear as early as 20 to 30 minutes after the injection, which, one notes, corresponds to the one-millimeter daily rate (40 micra per hour). These observations thus have succeeded in separating at least two different geographic pathway systems for the newly synthesized proteins. Correlated with these data, Droz has found different residence times of two classes of protein within the cell soma: a transitory population that leaves the soma within one day, and a second group that occupies the cell space for about two weeks. Tentatively, one might identify the short residence group with the protein components of the moving axonal matrix, perhaps including neurofilaments, whereas the population of longer residence would go through the serial changes in which, according to Droz, newly synthesized protein is being "accumulated, segregated and conjugated" in the Golgi complex. While the establishment of this clear-cut dichotomy among classes of protein marks a significant forward step, our technical inability to discern finer subspecifications within each class remains a major challenge for the future.

FUNCTIONAL ADAPTATION Thus far I have dealt with the chemical production machinery as if it were autonomous. Ever since the classical experiments of Hydén and his collaborators, however, it has been evident that the intensity of protein synthesis in the neuron varies sensitively with the level of functional activity (Hydén, 1967). Increased activity expresses itself not only in chemical terms in a rise of RNA and protein, but also in morphological changes, such as enlargement of nucleolus, nucleus, and perikaryon. This hypertrophy is evoked by prolonged excitation (Hamberger and Hydén, 1945), as well as by increased trophic demands upon the neuron, such as during the regenerative regrowth of a severed nerve fiber (Murray and Grafstein, 1969) or when neurons are made to take over a larger area of terminal innervation by profuse peripheral branching (Wohlfahrt and Swank, 1941; Edds, 1950). Reciprocally, reductions of the load or demands placed upon the neuronal soma manifest themselves in a lowering of the production rate, which in favorable cases (e.g., after permanent severance of a nerve fiber with blockage of the regeneration of the stump) is marked by size regression (Weiss et al., 1945) proceeding from nucleolus to nucleus to perikaryon and finally to the caliber of the axon (Cavanaugh, 1951). The so-called "axon reaction" after the transection of a nerve fiber is a composite of this regressive phase, superseded rapidly by the progressive changes subserving the regenerative process.

PROTEIN SYNTHESIS IN EXPLANTS In order to extricate the neuronal cell bodies from the network of complex

relations in the whole animal, we have tried to extend the analysis to isolated nerve centers in vitro with a minimum of trauma. Postnatal spinal ganglia of mice or rats, explanted with their capsule into nutrient solutions, proved to be adequate for the task. In the presence of tritiated leucine, their radioactivity mounted according to a regular, repeatable time course, becoming stabilized two to three hours after explantation (Weiss, 1967b). At the time, more than half of the labeled amino acid was found to be actually incorporated in ganglionic protein. Unexpectedly, it took as long as a three-hour chase in ordinary nonradioactive leucine or even leucine-free balanced salt solution to rid the ganglion of the nonincorporated remainder. Extending the tests to other tissue samples of about one cubic millimeter or less, we found that spinal ganglia, spinal cord, peripheral nerve, liver, and muscle fragments had time courses and saturation levels of protein neosynthesis that were characteristically different for each type of tissue (Weiss et al., in preparation).

Fragments of peripheral nerve, the axons of which had to be assumed to be nonparticipating in protein synthesis, gave the highest values. This made us suspect that the Schwann cells surrounding the axons have an inordinately high rate of protein synthesis. To test this presumption, we compared fragments of normal nerve with those of distal stumps of nerves severed two weeks previously, so that their axons had degenerated and been replaced by hypertrophic Schwann cells. Counts of radioactive protein per microgram (after immersion for two hours in ³H leucine, followed by a one-hour chase) were proportionately higher in the degenerated, axon-free, samples than in the normal, axoncontaining ones. The high rate of protein neosynthesis in peripheral nerve must therefore be allocated to the Schwann cell (and associated endoneurial cells), without any demonstrable participation of the axon.

The most puzzling results, however, were obtained when we compared protein synthesis in live tissue samples with that in tissues frozen solid on dry ice, kept frozen over night, and then thawed (Weiss et al., in preparation). It turned out that the specific differentials according to tissue types among the different parts of the nervous system, liver, and muscle were fully retained in the devitalized samples, whereas the differences between the frozen samples and the live controls for the same tissue were negligible; the only exception was peripheral nerve, in which the values for the frozen fragments were distinctly lower than those for their live counterparts.

These few examples may illustrate the puzzles and surprises we have encountered in our tests of explanted tissue fragments. I therefore shall not dwell on them further except for one set of experiments of such potential significance for pharmacology that it deserves to be added here. In the presence of sodium barbital, the radioactive count after two hours was only about half that of the control; and neural tissue fragments that were first labeled and then supplemented with barbiturate, leaked appreciable amounts of protein into the medium, the correspondence between the exuded and the retrieved amounts having been verified by radioactivity counts. Comparable tests with liver fragments indicated that the leakage is distinctive of neural tissue, being about 15 times greater from spinal cord and sciatic nerve than from liver. This investigation on a hitherto unsuspected action of narcotics should be extended with more refined techniques.

Having now briefly exemplified both the potentialities and the limitations of studies of the production plant of the neuronal cell body, with all their capriciousness and variability according to the techniques used (e.g., pulse labeling vs. homogenate assay vs. explantation), ostensibly aggravated by our lumping measurements of many disparate component processes under a common blanket, let us now look at least at some of the neuronal components that can be singled out because of their structural characteristics—the organelles.

Neuronal organelles

The study of neuronal organelles and other inclusions is, of course, subject to the uncertainties of the electron microscope technique, which, depending on the state of the tissue and the methods of fixation, exaggerates certain finestructural features, while failing to record others. The extent to which physiological fluctuations of the internal milieu, for instance, might affect the electron-microscopic visibility of a given fine structure in nerve has rarely been taken into consideration. Due allowance for such variability is made in the following brief account.

MITOCHONDRIA During unimpeded axonal flow, ultrathin sections of myelinated axons show an average of two mitochondria per section. However, when the flow is locally dammed up, many hundreds of mitochondria pile up within a few days in the sections immediately upstream to the obstruction (Weiss and Pillai, 1965), proving that the axonal flow carries the mitochondria from the perikaryon cellulifugally (Kapeller and Mayor, 1967). Besides passive carriage, mitochondria may exhibit some independent local motility within narrow range (Pomerat et al., 1967). Arrested in their convection, they rapidly degenerate (Weiss and Pillai, 1965). We find the same accumulations and disintegrations also at the nerve endings (Mayr and Weiss, in preparation). Density and cellulifugal convection rate of mitochondria at the axonal flow rate (1 mm = about 1,000 times mitochondrial length, per day, or one mitochondrial length per minute) indicate a daily production rate of mitochondria within the cell body in the

neighborhood of 500. Mitochondrial enzymes, such as succinic acid dehydrogenase (Friede, 1959) and DPNdiaphorase (Kreutzberg, 1963), have been recovered in high local concentrations at the upstream ends of blockages of axonal flow, which now is readily explained by the local accumulation of their carriers.

After disruptions of nerve continuity more violent than the mild constrictions used in our method, e.g., after a tight ligature, crush, or transection (Lasek, 1967), fleeting accumulations of mitochondrial and other enzymes have been observed at the distal end of what in these cases is a traumatized tissue segment (Lubińska et al., 1963). To ascribe this, without further evidence, to a reversal of axonal flow in the distal stump, is gratuitous: the upstream navigation of a power-driven riverboat does not signify that the river is flowing backwards. Conceivably, the distal accumulation, which subsides within a few days, could be explained as follows. The breakdown of the damaged nerve segment establishes a local center of high acidity and electronegativity, which attracts mitochondria toward the lesion by galvanotaxis, and perhaps positively charged molecules, including some enzymes, by the familiar "demarcation," or injury current, of severed nerve fibers. Although as yet unsupported by direct experiments, this or some similar explanation seems superior to "flow reversal," which is contradicted by all direct observations on mature nerve fibers (Mayor and Kapeller, 1967).

The breakdown of mitochondria at the blind distal end of axons raises a crucial question, already alluded to above: as they disintegrate, to what extent does their content of DNA, RNA, and nucleotide molecules undergo decomposition? Considering the evidence for some autonomy of protein synthesis in nerve endings (Barondes 1969), is it not conceivable that some residual, undecomposed transcription and translation machinery for protein synthesis is released from the disintegrated mitochondria and activated in situ? If true, this notion would still leave the nucleated soma of the neuron with a monopoly for macromolecular reproduction, expanded by shipping a subsidiary branch factory to an outlying location.

NEUROTUBULES The "neurotubules" (neuronal microtubules) are relatively stiff structures of \pm 220-Ångström diameter that run the length of the axon in bundles and are frequently associated with mitochondria. Their composition and structure are dealt with by other contributors to this book. As a tentative concept of their origin, I submit that they grow forth continuously from bases in the nucleated soma by a process of stacking onto their open central ends the near-globular subunits (Schmitt and Samson, 1969) of which they are known to be composed; these units might well be part of that protein population of prolonged cytoplasmic residence commutated on its passage through the Golgi body. *Pari passu* with this accretion at its root, the finished stem of the tubule would be drawn out continuously toward the periphery by the axonal flow. Such growth of elongate structures from their basal ends is common in organisms (for instance, the growth of cilia from their basal bodies). This concept implies that the number of neurotubules along the whole length of a given axon cannot increase. In other words, peripheral branching of neurotubules on an extensive scale could not be expected, although an occasional apical fission might be envisaged.

To test this premise, we have made counts in serial sections of axons with near-terminal branchings (Mayr et al., in preparation). As predicted by our concept, the sum of neurotubules in the branches was equal, within the limits of counting error, to the total number of tubules in the common stem. Thus, even though the axon branches, the individual neurotubules do not. Another requirement for the concept is that if the driving mechanism for the axonal advance is paralyzed, while the central addition to the base of the neurotubules continues, a tangle of twisted neurotubules should be observable in the cell body.*

Notions about the configuration of the distal ends of neurotubules are vague. Mechanical considerations intimate that the tubule is closed. If it serves as a canal for substances to be discharged at the end, that distal lid must be assumed either to undergo intermittent rupture or else to become pinched off, forming the wall of a vesicle. Evidence for the latter alternative, directly bearing on the formation of synaptic vesicles, has been advanced (Pellegrino de Iraldi and De Robertis, 1968) and the actual pinching off of such vesicles from the blind ends of neurotubules, closed by a constriction of the nerve, has been observed (van Breemen et al., 1958). However, the identification of such vesicles with true synaptic vesicles is still debatable.

NEUROFILAMENTS In contrast to the straight neurotubules, the neurofilaments, 70–100 Ångström units in diameter, show a more wavy course. They also seem to run continuously and unbranched from the cell body to their terminations. The evidence for this is found in our recent observation that, at least in certain types of peripheral nerve fibers, the neurofilaments are spaced at very regular lateral intervals from one another, the histogram of the intervals showing a sharp peak at 428 Ångström (Weiss et al., in preparation). The geometry of this grid suggests either the presence of longitudinal channels (unresolved in the electron microscope) in the matrix between them or a sort of linear macrocrystalline organization of the matrix itself, as seen in other ground substances (Weiss, 1968, pp. 24–122), but nothing further can as yet be said about this regularity.

* Isotope labeling of colchicine-binding protein of neurotubules has confined their advance at the one-mm rate (J.-O. Karlsson, unpubl.). INTERTUBULAR CANALS The suggestion of such 400-Åwide spaces parallels another system, better resolvable by the electron microscope, of longitudinal canals of about 600-800-Ångström diameter ("inter-tubular canals"), which we have seen in the matrix of certain axons in overosmicated preparations (Weiss, 1969a); both in location and size order, these correspond to the highly regular "honeycomb" cross sections observed in axons, both central and peripheral, in a considerable variety of pathological conditions (Morales and Duncan, 1966; Hirano et al., 1968). In line with our earlier comments about electron-microscopic visibility, one might assume that this canalicular system is a true microstructural system, the electron-microscopic demonstration of which is marginal in normal nerve, but is improved by more favorable local conditions of a pathologically altered internal milieu.

Fast traffic

The presence of such preformed channels in different types of neurons is intimately related to the demonstration in recent years of fast transport routes between cell body and nerve endings. Various radioactively labeled substances were found to span that distance at speed some 100 times as fast as the one-millimeter advance of the axonal column itself (Miani, 1964; Dahlström and Häggendal, 1967; Karlsson and Sjöstrand, 1968; Lasek, 1968; McEwen and Grafstein, 1968; Ochs et al., 1969). In such cases, the velocity curve of labeled proteins showed two separate peaks, one registering the standard one-millimeter daily rate of the axon, the other signaling the faster traffic. There are thus at least two distinct traffic systems in operation. Whether the traffic rate in the fast system of a given axon type is uniform is not yet known. The velocity curve of the axonal advance itself, however, spreads out with time (Taylor and Weiss, 1965), which indicates rate differences among the individual fibers of a given nerve. Moreover, according to cinemicrographic recordings of axonal flow, the velocity within a given axon seems to decline transversely from the central axis toward the surface.

In this connection, it should be noted that since the axonal advance represents *volume* flow (ca. 10 cubic micra per minute), that is, displacement of three-dimensional mass, measurements in linear (e.g., *millimeter*) units disregard variations in the cross-sectional area. In first approximation, this has been acceptable. However, with greater refinement of our knowledge, the caliber of nerve fibers will have to be taken into account. This point is illustrated, for instance, by the comparison between axonal flow rates in young and old rats, which, in measurements on the linear advance scale, suggested a marked decline with age (Droz, 1969). However, since the caliber of nerve fibers increases steadily with growth, an average increment of 60 per cent would readily

account for the observed linear deceleration, even if the daily volume outflow from the cell body remained constant. In the same sense, linear velocities in submicroscopic narrow channels within the axonal matrix need not indicate particularly high production rates of the substances in question. This is one reason among many why the fast transport observed must be viewed as an intra-axonal phenomenon, not to be confounded with the flow of the axonal matrix. Neurotubules, intertubular spaces, and similar continuous channels from cell body to periphery are logical candidates for the role of pipelines for substances to be shipped in solution from the manufacturing center to distant work stations.

As Kreutzberg (1969) in my laboratory has shown, the neurotubules qualify in that sense. On the premise that neurotubules share their main properties with the microtubules of other cell types, and considering that the motility of the microtubules that constitute the spindle fibers of the mitotic process can be immobilized by colchicine, minute amounts of this drug were injected into peripheral nerves. This blocked the passage down the axons of acetylcholinesterase locally within the injected stretch, but did not interrupt the continued flow of the axon itself, as evidenced by the continued downward progress of the mitochondria, assayed by their enzymes. The piling up of catecholamines in their production center in the neuronal soma after colchicine treatment (Dahlström, 1968; Karlsson and Sjöstrand, 1969) leads to a similar conclusion.

Transport mechanisms

These considerations of possible traffic routes are intimately related to the question of the physical conveyor mechanisms effecting the cellulifugal substance transfer. The bimodal rate distribution between the slow axonal convection and the fast intra-axonal conduction (see above), indicates that each is actuated by a separate and independent mechanism. The blockage, by moderate dosages of colchicine, of one but not the other supports this view. There is, moreover, evidence for a retrograde, cellulipetal transmission of "messages" along the axon, not explicable in terms of standard impulse transmission, which calls for a third axonal communication system, although not necessarily one involving molecular transfer. The three systems, therefore, are reviewed here separately.

NEUROPLASMIC FLOW As stated in the beginning, the quantitative mechanostructural analysis of the deformations resulting from the constriction of axons has conclusively proved that the solid axonal matrix—and, as mentioned earlier, presumably also part of the associated water—move as a single cohesive, viscous, somewhat plastic, body within the Schwann (or glia) cell, with or without an interposed laminated sheath of myelin. On elementary mechanical principles, a unidirectional translatory movement of such a column can result only from propagated waves of pressure differentials (e.g., traveling contraction-relaxation oscillations) sweeping unidirectionally over its length. The prototype of such a drive is a peristaltic wave. The pertinence of this model for axonal flow is documented (a) by the fact that the movement continues in isolated fragments of nerve, and (b) by the observation that when two ligatures are placed around a nerve in tandem, exoplasm dams up at the "upstream" sides of both the upper and the lower block (Weiss and Hiscoe, 1948; Dahlström, 1967; Mayor and Kapeller, 1967). This evidence would not be fully conclusive if it were based only on nerves studied in toto (Dahlström, 1967), as part of the fibers might have remained unconstricted, hence unblocked, at the upper level; but our original demonstration (Weiss and Hiscoe, 1948) of tandem damming in single fibers of doubly constricted nerves removes that reservation. We know, therefore, that the contractile energy must be available at every level of the axon, but be activated "domino"-fashion in cellulifugal direction. As a model for such a self-propagating process, I have suggested a chemomechanical energy transduction in incompressible fluid bodies covered by lipid-protein membranes (Weiss, 1964). The nerve fiber could satisfy the conditions of the model.

Although actual proof for this or any other hypothetical mechanism of the drive is still lacking, the sheer fact of its peristaltic character has been rather well established, as it could be directly recorded visually by time-lapse cinemicrography of living, mature, myelinated nerve fibers (Weiss et al., 1962; Weiss, 1963). Representative scenes from the vast footage of film taken in this manner over the years by my collaborators (mostly A. C. Taylor, M.D. Rosenberg, and A. Bock) have been shown on many occasions and are being prepared for more general circulation. Only the most pertinent observations can be reported here. (1) The constrictive wave definitely travels over the surface of the axon, involving visibly both the myelin sheath and the axolemma. (2) The axonal content itself is propelled passively by the surface wave; for instance, if a local obstruction (e.g., a kink or a fold) impedes the smooth advance of the content, the axonal column on the upstream side of the block becomes longitudinally compressed and dilated until its pressure head at the block overcomes the obstruction and the whole column can again proceed. (3) In the early phases of Wallerian degeneration of fibers severed from their central cell bodies, each of the fragments (Ramón y Cajal's "ovoids"), into which the fiber breaks up, continues to show peristalsis. (4) In all axons thus far observed, whether intact or fragmented, the frequency of the surface waves is the same and remarkably constant, with a mean duration of 17 minutes per cycle (i.e., three to four pulses per hour), at a mean velocity of propagation adequate to account for the common axonal flow rate of 50-100 micra per hour. In contrast to the continuity and regularity of the drive, the actual advance of the content varies with local conditions of the traffic channel, and hence appears to proceed in spurts. (5) No records have as yet been taken of unmyelinated fibers. (6) The paucity of mitochondria in the axon, in contrast to their great abundance in the Schwann cell, makes one favor the latter as the source of the energy supply for the peristaltic drive. On the other hand, many observations, calculations, and mechanical considerations tend to discount the possibility that the Schwann cell with its pulsation (Pomerat, 1961), which it has in common with other cells observed in vitro (Weiss, 1961a), is of itself the driving mechanism; it just provides the fuel, as it were, but not the machine.

With the cinemicrographic data on hand, we have gone on now to construct a hydrodynamic model to reproduce the peristaltic axonal drive to allow a quantitative study of the major variables. Save for a few theoretical treatments of very recent date (Fung and Yih, 1968; Shapiro et al., 1969), the assumption that a superficial pressure wave and deformation of small amplitude could set and keep the interior mass in flowing motion has not been substantiated. Our mechanical model (constructed with the collaboration of Professor Martin Levy and Mr. Robert Biondi of my staff) has now verified that assumption, opening a direct technological approach to the finer analysis of the parameters of axonal flow. In combination with our cinemicrographic studies (not reviewed here) of shifts of the axonal content produced artificially by localized pressure on explanted nerve pieces, we have reasons to expect an early substitution of solid information for the current vague conjectures about the mechanism of axonal flow.

FAST-TRAFFIC MECHANISM Unfortunately, the same optimism hardly seems warranted in respect to the mechanism of fast intra-axonal transport. I have given above the fine-structural indications for preformed transport channels, such as the neurotubules and intertubular spaces, but even if confirmed in their role, their operative mechanism would still remain conjectural. The physical preconditions for traffic in those submicrodimensions (Weiss, 1969a) are so exacting that no incontrovertible explanation is presently in sight. An ingenious speculation, implying the faculty of microtubules for propelling larger particulates on their outsides, has been suggested by Schmitt (1969). However, the general applicability of that hypothesis seems questionable in the light of the extensive observations made in our laboratory by Green (1968) on the role of the microtubules of pigment cells in the massive concentration and dispersion movements of the large (one micron) pigment granules in response to drugs; in these experiments, a constraining role
of microtubules on the orientation of the granular displacements was unmistakable, but analyses by the electron microscope and by cinemicrography failed to substantiate a motile role of the tubules in the propulsion of the granules. My own, no less speculative, proposal for a motile mechanism of tubules for intratubular convection is the following. If we accept the current thesis that globular protein subunits compose the spiral chains of which the walls of the tubules presumably consist (Shelanski and Taylor, 1968), we need only presume that (1) a chemical, electrical, or mechanical energy input at one end produces a change in molecular conformation, which entails a reduction of molecular volume, and, hence, a closer packing, i.e., a local constriction of the tubule; (2) some tubular content is thereby squeezed out into the neighboring sector of the tubule; (3) the conformational change, which started at the base of the wall, triggers a corresponding change at the adjacent level, resulting in a constriction of the latter; (4) the content is thereby propelled further; and so forth, in what amounts to a peristaltic advance.

Because this scheme, although plausible, is no less unsubstantiated than any other, the safest answer to the question of fast intra-axonal transport mechanisms remains "We just do not know."

RETROGRADE MESSAGE TRANSFER In the matter of ascending information passed on to the neuronal cell body from its peripheral extensions in ways other than impulse conduction, we are just as much in the dark. The postulate of such a cellulipetal message service rests on (a) the "chromatolytic reaction" of the perikaryon of a neuron, which arises whenever a nerve fiber has been severed; and (b) the fact that the central cell body "knows" the specific type of peripheral organ on which its axon happens to have terminated (Weiss, 1965).

As I have indicated above, the notion of a reversed bulk flow as message carrier can be dismissed as unfounded. In fact, there is no reason for presuming that the communication relies at all on massive substance transfer. One possible mode of action might be the rapid passage of charged molecules along interfaces by an electrically actuated "molecular bucket brigade." We have found that in tendon, which consists of rhythmically banded collagen fibers embedded in a matrix of mucopolysaccharide, the spreading of molecules that carry a net electrical charge, but not of neutral ones, occurs preferentially and rapidly along the interfaces between fibers and matrix (Weiss, 1961a). Electron microscope analysis (Grover, 1966) suggested a saltatory transfer of the molecules from one heavy dark band of the collagen fiber to the next (a distance of 640 Ångström units), those bands marking the clustered positions of the polar amino-acid side chains. If a similar phenomenon could be demonstrated for nerve, the interfaces between neurofilaments and axonal matrix might qualify as the "message

carriers," which, incidentally, would also allow us to assign a useful function to the neurofilaments.

Whether applicable to nerve or not, the unexpected expedition of molecular transfer along interfaces in tendon once more intimates how many more principles of basic relevance to the understanding of cellular dynamics may still be waiting to be discovered and how unwarranted it would be to rely solely on our present stock of knowledge for the interpretation of such novel problems as those which keep arising in the study of neuronal dynamics.

The fate of the neuronal substance

One of the problem areas is, of course, the fate of the axonal material that is incessantly flowing down from the perikaryon. It makes up about 15 per cent of the mass of the axonal column, the rest being water and small molecules diffusing in and out. Of that 15 per cent, an unknown fraction must be allocated to constituents of known fate, namely (a) transmitters of central origin, which are discharged, and (b) mitochondria, which break down. Furthermore, if we accept the concept that the neurotubules and neurofilaments are perpetually renewed from their perikaryal bases and commensurately disintegrated at their distal ends, we can also subtract their mass from the account sheet. Accordingly, the fate of no more than perhaps 10 per cent of centrally produced axonal substance remains to be accounted for.

This would be essentially the protein component engaged in the sustenance of the living state of the axon itself, i.e., largely the enzyme systems needed in local metabolism along the line. In view of the short half-life of neuronal proteins, counting by weeks (Lajtha, 1964), on the one hand, and the absence of local sources for enzyme replenishment for the enormous metabolizing mass of the axon on the other, one might have had to postulate a supply stream from a far-off factory, such as has now been empirically discovered. We, therefore, feel entitled to assign the major portion of the missing balance in our account to the repletion of the catabolically degrading units of the axonal enzyme population. If the *slow* axonal flow were the supply vehicle, uniform delivery over the whole length would require not only a flow-velocity gradient declining from axonal core to surface, for which there is some evidence, but also insulation of the traveling molecules against proteolysis during their long trek (circa one year from spinal cord to toe in man). If, on the other hand, enzymes are transported by the rapid intra-axonal system (note, for instance, the blockage of acetylcholinesterase by colchicine, reported above), questions arise as to their ubiquitous availability along the whole axon. So, it would seem best, for the present, not to speak of "enzymes" in that generality, ignoring the different needs, routes, distributions, and destinations for each class and, above all, to restrain commitment to speculative interpretations as long as no firmer ground on which to base it is at hand.

74 Axoplasmic Transport: Physical and Chemical Aspects

PETER F. DAVISON

THE SUBJECT OF axoplasmic transport has become popular recently and has been reviewed by several authors (Barondes and Samson, 1967; Schmitt and Samson, 1969; Weiss, 1969; Grafstein, 1969). My purpose is not to add to these reviews but to discuss certain aspects of the transport phenomena that merit further investigation and interpretation.

Neurons synthesize and turn over protein rapidly; after the local administration of radioactive amino acids to nervous tissue, neurons become densely labeled in comparison with satellite and connective-tissue cells (Droz, 1969). In studies on roach and crayfish, maximal protein labeling is achieved within hours and then much of the protein is catabolized again, but 10 to 20 per cent is long lived, and of this much moves from the cell body and along the axon (Smith, 1967; Fernandez and Davison, 1969). Proteins labeled in this way have been used by many investigators to study the process of axoplasmic transport in various animals. If cycloleucine is substituted for leucine or if the incorporation of 3 H-leucine into protein is blocked by puromycin, the movement of a labeled protein is not observed.

Many proteins move along axons at from 1 to 3 mm per day as Weiss and his coworkers found originally, but certain materials, often particulates, move more rapidly, and rates of as high as 2800 mm per day have been reported (Jasinski et al., 1966). The existence of "slow" and "fast" transport has led to the belief that there must exist at least two molecular mechanisms that move the contents of the axon distally. The characteristics of these processes are discussed below, but the justification for discriminating two mechanisms is considered in a later section with reference to the constraints that the experimental findings place on any mechanism that is postulated to explain the transport.

Experimental parameters of axoplasmic transport

DISCRETE LOCALIZATION Many experimenters have observed that labeled protein moves along the axon as a broad peak. Fernandez and Davison (1969), however, found that a small injection of very high specific activity ³H-leucine into a ganglion of the crayfish nerve cord leads to the synthesis of labeled protein over a brief period, and some of this protein is subsequently detectable moving caudad along the cord at 1.1 mm per day. For periods of up to 14 days, at 20°C, this moving column of protein is confined to a 1-mm length of cord (Figure 1). One characteristic of laminar flow

FIGURE 1 The distribution of 3 H-leucine incorporated into protein in 1-mm segments of the crayfish nerve cord. A. 12 days after injection of label into the third abdominal ganglion (the injected segment is hatched in the histogram and marked with an arrow is the diagrammatic representation of the cord above). B. 12 days after the label injection, as above, and 11 days after the injection of colchicine into the fifth ganglion. The normal 1.1 mm per day caudad movement has been interrupted at a distance of 4 mm from the colchicine injection site. The dashed line shows background counts.

PETER F. DAVISON Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts. *Present Address:* Boston Biomedical Research Institute, Boston, Massachusetts

in a tube is the parabolic velocity profile within the fluid: the liquid at the center of the tube travels at twice the average velocity of the contents of the tube, and the velocity approaches zero at the wall itself. This flow profile may be readily demonstrated by sucking a small volume of dye into a fluid-filled capillary (Figure 2). Such a dispersion of labeled protein certainly does not take place in the slowly moving protein of the axon, so we may dismiss the concept that this transport represents *flow* of dissolved protein driven by any mechanism. Furthermore, the sharp "front" of rapidly transported protein in the cat sciatic nerve, described by Ochs et al. (1969), precludes any flow process in this instance of rapid transport, as well. The coherence of the slow transport suggests that the axoplasm is gel-like, entirely consistent with the physical characteristics of extruded squid axoplasm (Huneeus and Davison, 1970). Alternatively, parallel mechanisms averaged over the whole cross section of the axon might effect a concerted transport that maintains a linear front.

CONSTANT VELOCITY The displacement of labeled protein along the axon from the site of synthesis can be mea-

FIGURE 2 The expected dispersion of a soluble labeled protein perfusing an axon under laminar flow is shown by the distribution, assayed at three different times, of dye injected into and then pumped along a water-filled tube 0.7 mm in diameter, 300 mm long (equivalent to the dimensions of a 14-mm-long, 30-micron axon in a crayfish cord). Each tube was cut into 1-cm segments, and the dye was eluted from each and measured. The spread results from the parabolic velocity across the tube.

sured with some precision as a function of time. Experiments on the crayfish have shown that the slow movement is linear with time up to at least 16 days. Many axons narrow progressively with distance from the soma, which may imply that transport rate is "independent" of axon diameter.

CONCENTRATION GRADIENT Peterson et al. (1967) have shown that no concentration gradient of protein can be detected in the cat optic nerve to account for protein transport. Furthermore, such a mechanism cannot explain a constant transport rate, and it could not be effective in maintaining flow over distances greater than a few centimeters.

PROTEIN GROWTH The progressive displacement of protein along the axon could be explained by the growth of filamentous protein structures from the soma. This possibility is negated by the failure of an inhibitor of protein synthesis acting in the soma to block slow transport (Peterson et al., 1967).

TEMPERATURE DEPENDENCE The rate of movement of protein in the crayfish cord as a function of temperature has been found to be proportional to the temperature (in degrees centigrade), except that movement ceased at 3° C, although it was readily observable (0.3 mm per day) at 5° C (Fernandez et al., 1970). The linearity with temperature could suggest that physical, as well as chemical, factors limit the rate, and the cessation of movement between 3° and 5° C could indicate the disruption of the transport mechanism. It may be noted that certain microtubules dissociate at low temperatures (Tilney and Porter, 1967).

INTRINSIC PROCESS Several investigators (e.g., Dahlström, 1967) have shown that rapid transport persists in a segment of axon defined by two ligations. The source of movement must therefore be sought among the structures within the axon, without immediate reference or reaction to the activity of the cell soma or termini.

COLCHICINE EFFECTS The interruption of the rapid transport process by local application of colchicine to a nerve has been reported by Dahlström (1968). Inhibition of the fast, and a lesser effect on the slow, processes have been reported by Kreutzberg (1969) and Karlsson and Sjöstrand (1969). On the other hand Fernandez et al. (1970) did not study the rapid transport, but observed that a local injection of colchicine inhibited slow transport for as much as 14 days and for 2 to 4 mm around the injection site (Figure 1). In view of the demonstrated binding specificity of colchicine for microtubule protein (Borisy and Taylor, 1967), the experiments strongly suggest the involvement of microtubules in the axon with some aspect of the fast transport process and the slow. COMPLEXITY OF TRANSPORTED PROTEINS Several authors have compared the rapidly and slowly transported axoplasmic constituents and have found a preponderance of particulate materials in the rapidly moving and soluble proteins in the slowly moving labeled fractions. In view of the tendency of certain of the axoplasmic proteins of squid to aggregate (Huneeus and Davison, 1970), this discrimination between particulate and soluble protein could be unreliable; therefore, Fernandez et al. (1970) dissolved the crayfish cord in 8 M urea and separated at least eight components in urea by gel electrophoresis. The specific activity of these proteins was roughly constant. In particular, no dip in specific activity was observed in the region of the gel where the microtubules subunit (a major protein component of the crayfish axon) was expected to migrate (Figure 3).

FIGURE 3 Gel electropherogram of protein labeled by injected ³H-leucine and isolated four days later from the slow-moving protein in the crayfish cord. The protein was extracted and analyzed in 8 M urea, 0.05 M mercaptoethanol (Fernandez et al., 1970). The histogram shows the concentration of tritium in 3-mm slices of gel; the graph shows the distribution of protein as revealed by dye-staining and densitometry. Clearly, a complex population of proteins of roughly uniform specific activity is present. The position where the microtubule protein was expected to move is shown by the arrow. The second and third sharp peaks on the left of the diagram correspond to the interfaces in the discontinuous gel.

It may be concluded that the microtubules form part of the population of slowly moving proteins that includes all the major protein constituents of the axoplasmic gel. It follows that the faster-moving proteins must be minor constituents, as has indeed been noted (McEwen and Grafstein, 1968).

BIDIRECTIONAL TRANSPORT Several workers have reported the accumulation of specific axonal constituents on both sides of a ligature, and have concluded that transport may be directed both toward and from the soma, although it is generally agreed that net transport is consistently somatofugal (see Lubińska, 1964; Dahlström 1967). The significance of these observations has been questioned (Weiss, 1969), so we do not take issue here on the implications of these observations for the mechanisms of axoplasmic transport. The observations of Lasek (1968), however, on axoplasmic transport in the bipolar cells originating in the cat dorsal-root ganglion show that, although transport is somatofugal, it is not always orthodromic. Therefore, if the transport is in any way correlated with, perhaps to sustain, electrical or transynaptic activity, the direction of the action potential does not define the direction of protein movement.

These observations on transport listed above clearly limit the hypotheses that are devised to explain the mechanisms of transport, if the constraints can be generalized to all species.

Possible mechanisms of axoplasmic transport

From the preceding discussion, we must conclude that the mechanism underlying the fast and, possibly, also the slow transport processes is present in any isolated segment of axon. It also appears probable that any energy-transducing mechanism capable of propelling a significant weight of axoplasm should be sufficiently structured to be resolvable by electron microscopy. The only consistent entities discernable by electron microscopy of axons are the axonal membrane, neurofilaments, microtubules, and occasional vesicles and mitochondria. The probability that any of the first three structures is involved is discussed below.

THE NERVE MEMBRANE Weiss has suggested that the propulsion of the contents of the axon may be effected by a slow (17-minute period) somatofugal, peristaltic wave that traverses the nerve membrane (see Weiss, 1969). The origin of this contractile process has not been defined precisely. It could arise from the neuronal or Schwann-cell membranes, although thus far no contractile proteins have been isolated from these sources. The propulsive efficacy of a peristaltic wave depends on the shape and constancy of the waveform and the consistency and thixotropy of the tube contents. An investigation of the correlation between the temperature dependence of the wave velocity and the transport process, and between the transport velocity and the axonal diameters, should be able to determine if the wave is responsible for the slow-transport process, but these experiments have not yet been performed. It appears plausible that peristalsis could account for the process by which the bulk of the axoplasmic constituents are moved (in the form of a gel). If such is the case, it appears that we must look for a second mechanism that transports selected components, which may be primarily vesicular, at a more rapid rate.

The possibility remains that a transport mechanism other than peristalsis originates at the cell inner membrane; the geometry of the situation requires that if this mechanism exists it probably drives the bulk transport rather than the fast, for the vesicular contents of the axon generally are not peripherally located. The mitochondria are an exception to this statement; they are often distributed conspicuously close to the axon membrane, a fact that supports the idea that energy-demanding processes occur at the surface. We do not know whether these processes include those concerned with axoplasmic transport or only those concerned with the maintenance of transmembrane bioelectrical processes.

MICROTUBULES Microtubules have been found to be prominent in many cellular regions where transport processes are found in various types of cells. They delineate the path followed by chromosomes in mitosis, by melanin granules in melanocytes, and by nuclei in a virus-induced cell syncytium (Holmes and Choppin, 1968). They also line the tentacles of the protozoan Tokophrya, where a rapid flow of cytoplasm occurs. These and other examples have been discussed elsewhere (Schmitt, 1968; Schmitt and Samson, 1969); in many instances, no organized structure but the cell membrane and the microtubules are detectable where materials are transported, and the possibility has been frequently voiced that the microtubules are the propelling agency. However, Porter and his colleagues, who have investigated microtubules intensively in many kinds of tissue, have interpreted the role of microtubules as cytoskeletal in most instances (Porter, 1966). Although the flexing of the tails of sperm, of flagella, or of the protozoan axostyle appears to relate to the microtubular structures they contain, the structures in these instances are paired or aggregated and adenosine triphosphatase activity has been observed in certain attendant structures (Gibbons and Rowe, 1965). It is, therefore, not obvious that the chemomechanical functions of these more complex microtubular structures can be extrapolated to the dispersed populations found in neurons and most other cells (see also Tilney and Gibbins, 1968). The only definitive claim that tubular structures in the axoplasm mediate transport of protein is by Kasa (1968). In this instance, however, the electron micrographs do not show characteristic microtubules but rather show irregular structures resembling smooth endoplasmic reticulum.

Very recently Tilney and Gibbins (1969) concluded that microtubules may be not a static cytoskeleton but the precursor and directive agency responsible for eccentric cellular outgrowth. This opinion leaves open the question of

their participation. Do they serve as a structure that merely constrains the direction of cytoplasmic movement, like a railway track, while the chemomechanical forces from some other structure power the movement? Or do they, as their specific binding of energy-rich GTP suggests, provide the motive power and direction for transport? Such a transport, moving stepwise along a filament, is familiar in the progression of a ribosome along ribonucleic acid during protein synthesis. Schmitt (1968) has recently postulated a translation mechanism involving an adenosine triphosphatasegenerating interaction between the subunits of the microtubule surface and selected particulates in the axoplasm that have the appropriate surface structure. The fastest transport rate in axoplasm would require a displacement across each subunit of the microtubule surface in approximately one millisecond.

NEUROFILAMENTS The possibility of the participation in transport along axons of neurofilaments, 100 Å in diameter, is suggested by their prominence in most axons and their lack of other known function. Moreover, other acidic protein filaments (albeit of smaller diameter, 30-60 Å) in the cytoplasm of amoeba (Morgan et al., 1967), nitella, and slime molds are believed to be implicated in cytoplasmic flow or streaming (Nagai and Rebhun, 1966). Indeed, Adelman and Taylor (1969) have isolated from Physarum the actin-like filaments and a myosin-like component with which they interact in a contractile process. Neurofilaments, however, are notably sparse in the narrow, sympathetic nerve fibers through which norepinephrine and its synthesizing enzymes are rapidly transported. Furthermore, they are also infrequent in developing neurites that, in their growth, must place heavy demands on the axoplasmic transport systems (Peters and Vaughn, 1967). (Droz, 1969, reported that transport is three times as rapid in young as in mature rats). In mature axons, the microtubules are partly replaced by an increase in the number of neurofilaments. This circumstantial evidence militates against, but does not disprove, the involvement of neurofilaments in axoplasmic transport. It is also improbable that neurofilaments and microtubules interact in any consistent manner, because they often are disposed in discrete assemblies and are not intermixed over an axon cross section. Schmitt and Davison (1961) suggested that material might move down the hollow core of these filaments, as they appear to run uninterruptedly from the cell soma to axon termini, but such a movement in a narrow channel presents a novel and unexplored hydrodynamic situation. If means of communication between the cell periphery and soma must be sought, the filaments remain a possibility, but their participation in somatofugal transport remains dubious. It is possible that their function is purely structural, providing the framework of the axoplasmic gel, for the maintenance of an extended

tube of cytoplasm without constrictions or collapse would appear to be a demanding process.

The replacement of microtubules by neurofilaments in the axons of a maturing animal, and the appearance of filamentous structures in the place of microtubules in colchicine- and vinblastine-treated animals (Wisniewski et al., 1968), have led to the speculation that the tubules and neurofilaments might represent two conformations of the same protein subunit. Such a speculation, at least, of all the speculations discussed in this paper, can be laid to rest. In experiments on the axoplasm of squid we have isolated the protein subunits of microtubules and neurofilaments after guanidine hydrochloride denaturation and shown them to be distinct by the following criteria: amino-acid composition (Table I), gel electrophoresis, and molecular weight (Davison and Huneeus, 1970). Antibody has been made to the denatured protein subunit (filarin) of the neurofilament; this antibody reacts with native and denatured filarin, but not detectably with the microtubule protein or with muscle actin. The difference between these filamentous structures is also emphasized by their markedly different ease of dissociation.

TABLE I
Amino-acid compositions of fibrous proteins
from squid axoplasm
(moles per 100 moles amino acid)

	_			
		Neurofilament *	Microtubules †	
Aspartio	: acid	13.5	9.4	
Threon	ine	5.2	5.8	
Serine		8.7	8.6	
Glutam	ic acid	16.9	12.6	
Proline		2.3	6.1	
Glycine		5.4	8.8	
Alanine		7.7	7.3	
Valine		5.1	5.5	
Cystein	e	1.4	1.5	
Methior	nine	5.9	2.6	
Isoleucii	ıe	3.5	4.0	
Leucine		6.5	6.5	
Tyrosin	e	2.0	3.0

* The averages of highly concordant analyses on three separate preparations of electrophoretically pure neurofilament preparations. † The average of two preparations, one obtained by preparative gel electrophoresis. In certain cases, agreement was not satisfactory, so that these values may need to be amended. OTHER MECHANISMS The fact that the prevalence of microtubules in cells was not generally recognized until glutaraldehyde was used as a fixative for electron microscopy should give us warning that we are not necessarily yet aware of all the apparatus with which the neuron is endowed. Indeed, J. D. Robertson (this volume) reports that Peracchia has found previously unrecognized septae across crayfish axons, the visualization of which depends on improved fixation. Therefore, we may not yet be aware of neuronal structures that may be responsible for one or another aspect of axoplasmic transport.

How many transport mechanisms?

Although the consistent observation that axoplasm moves 1 to 3 mm per day and the frequent detection of a faster transport process have led to the discrimination of "slow" and "fast" transport systems, it is noteworthy that the latter ranges from 10 to 3000 mm per day, and it is by no means obvious that these velocities can be mediated by one mechanism; and if they are, it must also be recognized that any mechanism that can span such a range of speeds might also drive the slow transport. To take an example, Burdwood (1965) has reported that the brief displacements of mitochondria in neurons by saltation have a velocity similar to the highest velocities reported in axonal transport. Thus, if there were some continuously functioning molecular machinery, such as a conveyor belt, with which the various axonal constituents associated intermittently and with characteristic frequencies, this same mechanism could drive material selectively with various speeds, and the normal "slow" movement of the mitochondrion would result from irregular and infrequent jumps at the "fast" rate. The two transport rates cannot be discriminated on the grounds that the slow movement is a bulk process, because the gel character of the axoplasm would insure bulk transport even if only one component of the matrix—the neurofilaments, for example—were directly propelled.

The existence of two independent mechanisms would be irrefutable, however, if they could be discriminated by function or drug sensitivity. Lasek (1968) has shown that the slow movement in a bipolar neuron occurs both orthodromically and antidromically at the bifurcation. If the rapid transport, which in some axons, at least, pertains to neurotransmitter, were directed only to the presynaptic region, there could be no doubt about the existence of at least two mechanisms, but this experiment has yet to be reported.

The pharmacological evidence is uncertain; studies show that both slow and fast transport processes are inhibited by colchicine (albeit, the fast at a lower concentration). Furthermore, microtubules were still observed by electron microscopy in the crayfish nerve cord treated with colchicine (although it remains a possibility that they were nonfunctional). Therefore, colchicine does not unambiguously distinguish two mechanisms or implicate microtubule function exclusively in either process. If, however, the slow transport is driven by peristalsis, it is probable that a second mechanism is available for the faster transport, and present evidence would suggest strongly that the microtubules are involved; in this case, the effect of higher concentrations of colchicine on slow transport could reflect the cytotoxicity of the drug (Angevine, 1957).

Conclusions

In summary, although there is convincing evidence for axoplasmic transport, the mechanism, or mechanisms, are unknown. It is likely, but not certain, that more than one distinct transport process occurs; the *slow* may be mediated by peristalsis in the nerve membrane and the *fast* may involve microtubules—but whether the microtubules define the direction of transport or the direction *and* propulsive power, and how they may do so, is not yet clear. Experiments have been discussed that could amplify our present knowledge.

An even larger problem remains unsolved: What is the function of the rapid turnover of protein in the neuronal soma, and what are the purpose and destiny of the proteins that are transported along the axons? Of the former we can say little. Of the latter, the slowly transported proteins are clearly a complex mixture representing, as mentioned above, most of the proteins in the axoplasm. Weiss (1969) has suggested that the slowly transported proteins may be consumed, during their passage down the axon, in replacing catabolized enzyme in the membrane and elsewhere, but our experiments (Fernandez and Davison, 1969) on the rate of depletion of labeled protein in its passage along the crayfish cord show that at least a significant fraction of the transported protein reaches the terminal segments of the axons. This result is not surprising, in that, if most of the slow proteins are destined to replace enzymes and other proteins, many should reach the synaptic regions because the synapse is clearly the site of considerable metabolic activity, whereas the only known function fulfilled by the axoplasm in the length of the axon is the preservation of the flow mechanisms and the viability of the axoplasm and the membrane. However other nonenzymic proteins reach the axon termini. A significant fraction of the protein traversing the axon is microtubule protein; whether its function is completed on reaching the presynaptic extremities or the subunits provide the raw material for other structures in the synapse is unknown. The intriguing possibility remains that certain proteins have functions not yet understood, and with further study new dimensions of neuronal function may be discovered. Among the compounds transported must be

those trophic factors influencing the postsynaptic cells, and any other agencies that may facilitate, restrict, or direct chemical transmission. Considerable evidence has been found relating drug-induced interruption of protein synthesis to a block in learning consolidation (e.g., Agranoff et al., 1967). The effect of such inhibitors does not demonstrate that protein synthesis itself is the mechanism by which memory is stored, but merely that it is a necessary concomitant to the processes by which storage occurs. Thus, further study of the protein metabolism of the nervous system gives promise of a better understanding of all aspects of neuronal function, and a characterization of transsynaptic activity may give insight into the coordinate activity of the brain that is the basis for higher nervous functions, including integration and learning.

75 Molecular Biological Approaches to Neurophysiological Problems: A Correlation

PHILLIP G. NELSON

IT WAS MY TASK at Boulder to suggest to the participants of the symposium on Molecular Neurobiology subjects at the cellular or system level of nervous-system functions that would be particularly rewarding as judged from the viewpoint of the neurophysiologist. In this brief essay, some of those points are discussed, as indicated at the outset of the symposium, and a few additional ideas are gleaned from the proceedings.

On the broad front of the symposium (and of the Intensive Study Program as a whole), the methods of molecular biology are being applied fruitfully to neurobiology, although particular psychological and neurophysiological problems, such as sensory coding, the mechanism of memory, and learning, are less susceptible at this time to that application. A case in point is the role of protein, generally considered to be the effector of the cell. No neuroprotein has been found that plays a central role in neuroscience, as, for example, myosin plays in myoscience. In this connection, G. M. Edelman argued that it would be better to mount a long-range program of characterizing brain-specific proteins one by one as they are discovered, rather than to seek a protein that, for hypothetical reasons, may be thought to play that central role. S. H. Barondes expressed similar views regarding brain glycolipids and glycoproteins. If, in the course of such investigations, he said, a protein of demonstrable importance is discovered, it will then be appropriate to apply the full armamentarium of molecular biological methods to its characterization.

The action potential mechanism

A problem central to neurophysiology and neurobiology, and one with a very long history, is that of the mechanism of the production of the action potential and its modulations that have been observed in neurophysiology. The importance of sodium, potassium, and calcium ions in the generation of the action wave itself has long been known. Hodgkin and Huxley (1952) have provided a quantitative treatment of the ionic movements involved in the action potential, and the ionic hypothesis has been of enormous value to virtually every practicing neurophysiologist. Tasaki (1968) has proposed an alternative hypothesis-the two-stablestate model of membrane excitability-because some of his experimental observations, particularly with internally perfused squid axons, seemed inconsistent with the Hodgkin-Huxley model. Tasaki has also attempted to incorporate some structural or molecular features into the bistable-state model of the neuronal membrane. A large number of elegant electrical measurements and manipulations have been made of internal and external ionic constituents surrounding the nerve membrane, but it is probably fair to say that these have not discriminated really decisively between the ionic hypothesis and the two-stable-state hypothesis of how nerve membranes work. It is interesting that in the laboratory represented by Keynes, and in Tasaki's laboratory, the techniques now being used for studying excitable membranes are directed explicitly toward the question of the membrane structures, the molecular species, responsible for excitability (Tasaki et al., 1968; Keynes, this volume). These include the optical methods, described by Keynes and Tasaki, which include light-scattering and birefringence studies and changes in fluorescent materials that have been incorporated in the membrane. McConnell's work on spin labeling of excitable membranes was also directed at this type of question. In addition, the studies of artificial systems involving lipid bilayers, which have been shown to exhibit some degree of excitability when treated with oligopeptides such as alamethicin, seem to offer great promise in demonstrating the molecular basis of excitability (Mueller and Rudin, 1968; Eigen, this volume).

In the analysis of central nervous system function, the mechanism of action-potential generation is frequently taken for granted. It is assumed that the action potential is required and is sufficient to conduct information between points in the nervous system; the various coding methods for conveying information by this all-or-none action potential are much studied. In general, however, the interpretations of such information transmission in the nervous system have not been concerned with the mechanisms of the action potential as such. Transmission of information by

PHILLIP G. NELSON National Institute of Child Health and Human Development, Bethesda, Maryland

axons across relatively large distances undoubtedly relies on an all-or-none, reliable, transmission mechanism. It is probable, however, that in central structures involving highly branched systems of axons—in particular at the axonal terminations—there are many points of low safety factor at which blocking of the action potential does take place. In fact, there is good evidence that at least intermittent blockading of conduction in branched axonal systems is, perhaps, common. Krnjević and Miledi (1958) showed that at the neuromuscular junction there is blockade at axonal branch points.

Old observations by Barron and Matthews (1935), and recent work by Raymond (1969) at the Massachusetts Institute of Technology, have demonstrated that intermittent conduction or periodic failure of conduction in axons occurs in the spinal cord. In the dendritic trees of neurons the question of partial conduction of action potentials is certainly very real. Llinás et al. (1968), Nelson and Frank (1964), and Nelson and Burke (1967), among others, have studied dendritic spike generation and have discussed the possibility that there is a wide variation in the coding function performed by neurons and that the variation depends on the different degrees of spike generation in the arborization of the dendrites.

With respect to modulations of the excitatory mechanism required in physiological function, it may be mentioned that the processes of accommodation and adaptation in neurons can play an important role in determining the behavior of a given neural system. "Accommodation" refers to a property of excitable membrane that causes the effectiveness of an excitatory stimulus to be strongly dependent on the rate of application of that excitatory stimulus. This property of accommodation varies considerably between different types of neural tissue, and in the motor control system of the mammalian nervous system it is differentiated in a functionally meaningful way. The motor neurons in the lumbosacral spinal cord can be distinguished in terms of the kinds of muscle fibers they innervate. Some motor neurons innervate slow-twitch, red muscle fibers, such as are commonly found in the soleus muscle; at the other extreme, some motor neurons innervate fast-twitch muscle fibers, such as are found in the gastrocnemius muscle. The mechanical properties of the soleus muscle unit seem optimally designed to provide the steady tonic contractions that are required for maintaining posture, whereas the mechanical properties of gastrocnemius fast-twitch muscle units seem much better designed for initiating movement, providing rapid bursts of high tension development. Almost none of the motor neurons supplying the slow-twitch soleus muscle fibers (type S) exhibit any significant degree of accommodation to slowly increasing excitatory input.

With regard to the motor neurons innervating the large amplitude, fast-twitch muscle units (type F), on the other hand, about half of the cells do exhibit substantial degrees of accommodation; that is, they respond much better to transient or rapidly changing excitatory stimuli and tend to be much less responsive to very slowly varying excitatory stimuli (Burke and Nelson, in preparation). In addition, when steady excitatory currents are passed across the cell membrane in these two classes of motor neurons, the motor neurons innervating the tonically functioning soleus muscle cells tend to show much more sustained repetitive firing than do the class of motor neurons innervating the fasttwitch fibers of the gastrocnemius muscle (Mishelevich, 1969). Thus, at the level of the membrane properties of the individual motor neurons there has been a differentiation in the property of the excitable neuronal structures such that the motor system has divided into a group of tonically firing muscle cells and a group of muscle cells that tend to be activated only transiently. Similar and probably functionally significant differences in the membrane properties of cortical pyramidal cells have been described by Takahashi (1965).

In vitro studies

Detailed study by molecular biological methods of neural systems such as that described above is extremely difficult, but there has recently been developed an in vitro preparation that shows some interesting properties and possibilities from the standpoint of studies of excitable membranes. Augusti-Tocco and Sato (1969) have worked with a tissue culture preparation of the mouse neuroblastoma cell line. I have been working with this preparation in collaboration with M. Nirenberg and B. W. Ruffner at the National Institutes of Health, and many of the cells of these cultures have been found to exhibit electrical excitability (Nelson et al., 1969). Examples of these properties are shown in Figures 1 and 2. Although the responses obtained did depend on the conditions of the recording, it appears that there is a true range of excitable properties in these cells. That is, under standard conditions of membrane potential and culture conditions, some cells show much more marked spike-generating activity than others, and some cells, indeed, showed essentially passive membrane properties. This preparation, therefore, may be a favorable one in which to study biochemical correlates of varying degrees of electrical excitability.

The physiological role of neuronal structural geometry

An area that should be of great concern to neurobiologists relates to those processes that govern the genesis and maintenance of the complex neuronal geometry so characteristic of the central nervous system. Both the elaborate dendritic trees and the highly complex axonal ramifications are

FIGURE 1 Mouse neuroblastoma cell. A. The cell is from a culture that had been treated with trypsin to dissociate the cells five days earlier. The cell was examined electrophysiologically soon after the culture had passed the logarithmic phase of growth. Total time in vitro was 108 days. B. An

active response. C, D. Examples of rectification. The lines labeled D and H indicate pulses of current that evoke changes in voltage across the cell membrane labeled d and h, respectively. S designates the steady current used to adjust the voltage across the cell membrane, s.

among the most striking features of the nervous system. The Scheibels (1969) have provided an elegant picture of neuronal configurations throughout the nervous system, and Ramón-Molinar (1968) has attempted to generalize about the enormously varied dendritic structures that he has studied in various portions of the nervous system. Possible common functions have been suggested for neurons that exhibit relatively regularly branched dendritic trees and those with more specialized tufted, wavy, or "idiodendritic" trees, which are seen in other portions of the brain.

Neuroplasmic flow

Both Weiss and Davison (this volume) have discussed the problem of neuroplasmic flow and the possible role of surface contractile processes or neurofilaments and microtubules in that flow. This neuroplasmic flow would certainly participate in the replenishment of materials at the synaptic junctions at the end of cellular processes, either dendrites or axons, and this would seem to be one of the important functions of the flow. Lumsden (1968) has raised the question of whether neurofilaments and microtubules may play some role in determining the branching patterns of axons. It might be that some relatively simple molecular instruction mechanisms utilize these fibrous proteins of dendritic and axonal processes to determine the form of even very complicated branched dendritic or axonal systems. Weiss has emphasized that surface contact and guidance phenomena undoubtedly are important in the generation of both branched systems and processes. It is obvious that the shapes of neurons in different parts of the nervous system are instrumental in determining the functions of neuronal sysstems, and the molecular basis for this highly elaborate cellular morphology is a crucial problem for molecular neurobiology.

Electrical properties of dendritic structures

An important problem in electrophysiology has been to determine some of the electrical properties of the neuronal dendritic structures. Wilfrid Rall (1967) has provided a quantitative mathematical model that is capable of dealing

FIGURE 2 A. The large, round cell, indicated in the photograph by the microelectrode, was studied. The culture was in the stationary phase of growth; total time in vitro was 66 days. B. Repetitive action potentials recorded soon after the cell was penetrated by the microelectrode. The action potentials took place in the absence of stimulating current. The

with these structures. Lux and I (Nelson and Lux, 1970) set out to answer two questions about these neuronal dendrites by examining motor neurons in the spinal cord of the cat. We wished to know, first, what percentage of the physiologically effective surface area of the cell was represented by dendritic membranes; second, how far away, electrically speaking, the ends of the dendrites were from this trigger zone in the cell body, i.e., what percentage of the synapses that occurred on the surface of the motor neurons were on the dendrites and how effective the dendritic synapses would be in initiating spike activity in the cell body.

It has turned out that between 80 and 90 per cent of the effective receptive surface of the motor neuron is on the dendrites and that even the farthest portions of the dendritic tree are only between one and two equivalent electrotonic lengths away from the cell body. The synapses appearing on the farthest portions of the dendritic tree thus have a steadystate attenuation factor of between about 3 and 9. The effectiveness of these synapses is attenuated, but even the synapses situated most distally have a significant effect on

broken lines represent portions of the records that were filled in during reproduction. C. Two action potentials elicited by a pulse of current. D. An example of "off-excitation." An action potential was evoked by turning off the pulse of current. The top of the action potential is not shown.

the spike-initiating zone in the cell body. The entire dendritic tree, therefore, is significant in terms of spike initiation and must be taken into account in attempts to relate dendritic structure to the possible functional properties of a given cell.

Specificity of interneuronal connections

Crucial for an understanding of nervous system function is the degree of specificity of connections between neurons. How carefully are the complicated axonal terminal ramifications and the dendritic trees of neurons interdigitated and how specifically are synaptic connections between the nerve cells regulated? Burke (1967a, 1968a) has looked carefully at the connections between sensory fibers from muscle and the motor neurons that innervate those same muscles. The experimental arrangement used in studying this problem is shown in Figure 3. This arrangement made it possible to record intracellularly with microelectrodes from individual motor neurons, to stimulate

FIGURE 3 Experimental arrangement for studying properties of cat spinal motor neurons and the muscle fibers they innervate. Circuitry to the left allows stimulation and recording of single motor neurons through intracellular electrodes (center). Strain gauge (SG) records mechanical activity of muscles. Abbreviations: MG, medial gastrocnemius muscle; SOL, soleus muscle; LG, lateral gastrocnemius muscle; CAL, calibration pump. (From Burke, 1967a.)

these motor neurons and record the tension developed by the muscle fibers they activate, and to record synaptic activity produced when different muscle nerves were stimulated either by electrical stimulation or by stretching the muscles to which the motor neurons were connected. As has been pointed out above, motor neurons can be divided on the basis of the characteristics of the muscles they innervate. If one looks at these groups of motor neurons on the basis of the nature of the synaptic connections from afferent sensory fibers, there also appears to be some differentiation. The synaptic potentials produced in motor neurons innervating the slow-twitch type of muscle units (type S) were larger and of somewhat longer time course than were the synaptic potentials produced in the motor neurons innervating the fast-twitch muscle fibers (type F).

An extensive study of the shapes of unitary postsynaptic potential generated by activity in a single afferent fiber has indicated that the time course is related to the location of the synaptic endings on the dendritic tree of the motor neurons (Burke, 1967b; Rall et al., 1967). Synapses that occur in the peripheral parts of the dendritic tree tend to produce slower, longer-lasting synaptic potentials because of electrotonic effect. Synaptic potentials generated by endings that are close to the recording site in the cell body are much sharper and faster. The longer time course of the synaptic potentials that are produced by stimulating the population of afferent fibers in the peripheral nerve indicates that a higher percentage of the endings on slowtwitch motor neurons are in the peripheral parts of the dendritic tree.

The differences in the time course of the postsynaptic potentials do not seem to be very dramatic, but if one looks at the summation of asynchronously occurring, unitary, postsynaptic potentials generated by muscle stretch, the effect of this differential localization of synaptic endings is considerable (Burke, 1968b). More substantial and sustained depolarizations take place in slow-twitch motor neurons, and repetitive activation occurs much more commonly and readily (Figures 4 and 5).

Thus, in this final output loop of the nervous system, in which the muscle fibers and the sensory fibers come from the muscle to end on the motor neurons, we have a functionally significant differentiation. The motor neuron membrane properties, the cell size, the axonal conduction velocity, the contractile properties of the muscle fiber, the specific connections of the afferent fibers in terms of the motor neuron with which they connect, and even the location of those endings on the dendritic tree have all been specified in such a way as to optimize the performance of the system. The slow-twitch motor system is optimized for the steady development and maintenance of contractions and fine gradations of this steady tension, whereas the fasttwitch system appears to be optimized for providing rapidly changing, high increments of tension that last for only a brief period; that is, their purpose is to initiate movement.

In addition, segregation of synapses on different parts of cortical cells, depending on the source of the synaptic endings, has been shown by Globus and Scheibel (1967a, 1967b).

Plasticity in neuronal function: use - disuse

An area of great interest to neurobiologists is that of plasticity in nervous function. Perhaps, in its simplest form, this may be put as the question of alteration of synaptic function as a result of use or disuse of the synaptic region. Can electrical activation of a synapse produce a long-term change in the efficacy of that synapse? Functional and morphological effects of altered activity have been demonstrated in the visual system (Hubel and Wiesel, 1965; Globus and Scheibel, 1967c; Cragg, 1969).

Recent work by Norman Robbins and Gerald Fischbach (in preparation) indicates that such synaptic plasticity does take place in a relatively simple preparation that allows detailed study of the relevant synaptic mechanisms. To demonstrate this, they used the neuromuscular junction of the soleus muscle of the rat. They showed that when the hind limb of a rat is immobilized by pinning of the ankle and knee joint, the activity of the soleus muscle of the limb, as recorded electromyographically, goes down by a factor of 20 or so. Because the electromyographic activity is the

FIGURE 4 Records from a type F medial gastrocnemius muscle (MG) motor unit illustrating "phasic" response pattern to maximum MG muscle stretch (about 14 mm extension from resting length). Records A and B: intracellular potential records (upper trace in each record), showing depolarizations produced by summated asynchronous EPSP activity during MG muscle stretch (signaled by deflections of the myograph tension record, the lower trace in each record). The unit did not fire to the stimulus either before (record A) or after (record B) a 15-second tetanus to the MG nerve at 250 pulses/sec. Calibration for A and B: 10 mV and 1–0 sec. Record C: EPSP response, again without spike (lower trace, arrow), elicited by sharp tap to the string connecting muscle and myograph (arrow in upper trace, which is MG tension record; tension change of about 100 g produced by a tap). Note that a reflex twitch of the MG muscle follows the tap, indicating that other units were activated by the stimulus. Calibrations: 5 mV and 50 msec. Record D: antidromic spike; calibration 50 mV and 1–0 msec. Record E: muscle unit twitch (lower trace) produced by intracellular stimulation (at artifact in upper trace); muscle at about 100 g passive initial tension, with background active tension suppressed by deep peroneal tetanus (see Figure 1B). Calibrations: 20 g and 50 msec.

FIGURE 5 Records from a type S MG motor unit (same animal as the unit in Figure 4) illustrating "tonic" response to MG stretch. Record A: intracellular record (lower trace) shows spontaneous firing without muscle stretch and more rapid sustained discharge during MG stretch of about 12 mm (signaled by deflection of tension record in upper trace). Calibrations: 50 mV and 1–0 sec. Record B: regular unit firing with small (about 20 g) tension on MG muscle, with an interposed EPSP and spike response (lower arrow) elicited by tap to the myograph string (at arrow in the

upper tension trace). Calibration: 50 mV and 50 msec. Record C: submaximal MG monosynaptic EPSP (lower trace) for EPSP wave form measurements. Upper trace is potential at the dorsal root entry. Record D: maximum MG EPSP recorded during blockade of antidromic invasion of the motor neuron with hyperpolarizing current passed through the microelectrode (hence the sloping baseline). Calibrations for C and D: 5 mV and 1-0 msec. Record E: muscle unit twitch response (lower trace) to intracellular stimulation. Calibrations: 2 g and 50 msec.

direct consequence of neural activity, the experiment shows that pinning of the limb reduces the activity of soleus motor neurons. They then looked at acetylcholine receptors in the postsynaptic regions in the muscles. The chemosensitive region or the number of acetylcholine receptors in the muscle increased. Thus, disuse leads to an increase in the number of receptors or a spread in sensitivity. They then studied the output of transmitter from the nerves coming from these disused muscles and found a drop-off in the ability of the disused nerves to maintain the output of synaptic transmitter in the face of repetitive stimulation. The number of quanta released per second is expressed as a function of the frequency of stimulation for the normal and disused junctions, as shown in Figure 6.

FIGURE 6 The relationship between frequency of nerve stimulation and transmitter output (in quanta per second) in the rat soleus nerve muscle preparation in vitro. Results are from normal muscles and muscles immobilized for the periods indicated.

This shows a fall-off of about 20 per cent in the ability of disused nerve to maintain transmitter output in the face of rapid repetitive stimulation. Quantal output may have been higher in the disused junctions at lower rates of stimulation.

Metabolic regulation of synaptic function

One of the most exciting aspects of this symposium was the discussion of the various ways in which synaptic function is controlled. There are several possible mechanisms by which electrical activity might relate to the metabolic events at the synaptic junctions and thereby regulate the effectiveness of the synaptic regions. Action potentials in extremely small structures, such as the presynaptic axons or boutons, would

864 ASPECTS OF MOLECULAR NEUROBIOLOGY

produce rather large changes in the ionic composition of both the intracellular and the extracellular fluids. With activity, sodium ingresses, which would be expected to stimulate the sodium- and potassium-activated adenosine triphosphatase. The consequent splitting of adenosine triphosphate could well affect a number of metabolic pools in the tissue. It has been shown (Birks and Cohen, 1968a; Dunant, 1969) that a blockade of the sodium pump by inhibitors such as ouabain promptly affects synaptic transmission, presumably because of intracellular accumulation of Na ions in the presynaptic terminal (Birks and Cohen, 1968b). Complex changes in spontaneous and evoked endplate potentials begin within a matter of minutes, and in an hour or so the spike-generating mechanism is blockaded.

The protein synthetic mechanisms in the synaptosome have been shown to be sensitive to the concentration of Na or K ions in the incubating medium (Shooter, this volume; Morgan and Austin, 1968; Appel et al., 1969). In contrast to the sensitivity of the ribosomal protein-synthesizing system, in synaptosomes the optimum concentration of sodium for incorporation of radioactive amino acid into protein is high (50mm or more), which is more than one would expect to find intracellularly under normal conditions. If repetitive spike activity occurred in a very small structure, such as a synaptic ending, intracellular concentration of sodium ion could increase appreciably. This increase could reasonably be expected to stimulate protein synthesis in the synaptic ending, which would provide a natural way to couple electrical activity to biochemical activity. Kakiuchi et al. (1969) have shown that electrical and chemical stimulation of brain slices increases the level of cyclic adenosine monophosphate in the slices by a factor of 10 or so. The mechanism of this stimulation is not worked out, but production of cyclic AMP clearly could be expected to affect many metabolic processes in brain tissue. This, therefore, represents another mechanism whereby electrical activity could be coupled to metabolic activity. Whittaker (this volume) has discussed the preparation of synaptosomes and of constituents of synaptosomes. These preparations are favorable for the study of synaptic function and plasticity. The relationship of electrical activity to metabolic activity in neural structures can clearly be approached by presently available techniques.

Connectionistic versus distributed, parallel processing in brain function

The kinds of questions discussed here arise naturally and inevitably from one concept of the nature of brain function, namely, the cellular, connectionistic model of central nervous function. This view of the central nervous system holds that the processing of information by the brain is determined by the specific patterns of converging and diverging connections between different nerve cells at different levels of the brain. That framework has undoubtedly been successful when investigators are dealing with the handling of information in the specific sensory systems (Hubel and Wiesel, 1962) and motor control systems. It is reflected in the theory of the "command neuron" in invertebrates (Kennedy et al., 1969) and perhaps has been carried to its extreme by Wickelgren (1969) in supposing the existence of "concept neurons." Various patterns of synaptic convergence and divergence are considered to result finally in the firing of a single cell, the activity of which could relate to a single specific, even a very complex, concept or high-order mental construct.

Experimentally, however, the single-cell approach to understanding brain function encounters severe difficulty as one goes from the specific sensory motor system to the higher associative areas of the brain. Even if the firing of a single cell were uniquely related to some complex configuration of events in the external or internal world, the possible combinations of events become effectively infinite and experimentally unapproachable. As the possible kinds of stimuli become larger than the stimulus represented by particular sensory modalities, it becomes impossible to determine the unique set of events that would be most appropriate to trigger the firing of a given cell. This is an ad hoc, or nontheoretical, quality of the specific connectionistic model of the brain that makes it extremely difficult to generalize, except in a vague way, about how the "associational" brain functions. In addition, some observations seem to pose a serious challenge to the specific connectionistic view.

The experiments of Lashley (1929) have been taken to pose such a challenge. The deficits in psychological functions produced by circumscribed lesions appear to be not nearly so specific as one might expect. That is, similar deficits may result when similar amounts of tissue are taken from rather different areas of the brain, so that a degree of equal potentiality of cerebral tissue was postulated by Lashley. Several criticisms of these experiments and their interpretation have been made (see Kandel and Spencer, 1968). John (1967) and John and Morgades (1969) made electrical recordings from widely distributed sites in the brain, and found relatively similar electrical activity as a correlate of various discriminative performances of trained animals. This was interpreted as indicating a more global, distributed, homogeneous response of the brain in distinction to what might be expected in a highly specific connectionistic model of brain function. An analogy has been drawn between this sort of distributed storage of information and that represented by the photographic technique of holography. Longuet-Higgins (1968) has shown that principles similar to those underlying the hologram can provide a basis for a distributed storage of temporal information.

space in the brain has a highly specific macromolecular composition and that important aspects of brain functions are mediated by this extracellular matrix of macromolecules. It might be expected that mucopolysaccharides and other macromolecules in the extracellular space and large molecules on the surface of neurons would be altered by electrical activity of nerve cells, and thus represent a possible substrate for the storage of information. That is, memory could reside in this extracellular compartment. Experiments of Baylor and Nicholls (1969a, 1969b, 1969c) on the central nervous system of the leech indicate clearly that interactions between nerve cells and glia may be mediated by extracellular accumulation of potassium resulting from the activity of nerve cells, and they raise the question of whether there may be a relationship between glial cells and specific groups of neurons that may be coupled by this glia-potassium mechanism. Extracellular current flows certainly mediate some degree of interaction between nerve cells, as has been shown in spinal motor neurons (Grinnell, 1966; Nelson, 1966).

Specific connections between nerve cells undoubtedly play a dominant part in the processing of information by the nervous system. Nerve cells, however, exist in a complex milieu, and extracellular ionic and macromolecular constituents undoubtedly play an important, still largely unexplored, role in modulating and modifying the function of the neurons. To discover if extracellular constituents and glial cells play a *primary* role in neural transactions remains a challenging aspect of molecular neurobiology.

Molecular Neurobiology: An Interpretive Survey

FRANCIS O. SCHMITT

THE SYMPOSIUM ON MOLECULAR NEUROBIOLOGY, with its associated plenary lectures, was productive of many new facts and concepts brought out in the lectures and informal discussions. This summational essay—not a review—must perforce be selective in the subjects and material to be treated; many interesting aspects will not even be mentioned, although some ideas generated after the symposium are included.

The division of the material into four sections---membranes, neuronal junctions, neurobiosynthesis, and neuroplasmic kinesis---is arbitrary, but the manuscripts group agreeably in this way. The order of discussion of individual papers is not the same as that in which the papers were presented.

Membrane systems

Until recently, ideas about the molecular organization of cell membranes followed a rather simple model. In 1925, Gorter and Grendel maintained that the cell membrane was only a few molecules thick. That it contained thin layers of "protein" as well as a bilayer of mixed lipid was suggested by Danielli and Davson (1935). Their theory was made highly probable by polarization optical and X-ray diffraction analyses of myelin membranes (Schmitt and Bear, 1939; Schmitt et al., 1941). The structure, seen in the electron microscope as two parallel dense lines, was popularized as the "unit" membrane by Robertson (1967).

The lipid-protein trilamina, which forms the continuous portion of the cell membrane, may be referred to as the *matrix*. From the outer surface of the matrix, stringy chains ("fuzz") of glycoprotein or glycolipid may extend for varying lengths (see Figure 1). This integral part of the membrane plays an important role in the cell's interaction with its microenvironment and with other cells (Schmitt and Samson, 1969). Upon or within the film matrix are situated such molecular devices as ion carriers and permeases, ion pumps, receptors, and other equipment to carry out special functions, e.g., the propagation of the nerve impulse. Much remains to be discovered about cell membranes. For example, do they contain DNA (only recently discovered in mitochondria) or RNA? Where is adenyl cyclase situated relative to receptors and the sources of its substrate adenosine triphosphate (ATP)? The special devices (pumps, permeases, and so forth) are thought to be distributed sparsely (about several dozen per square micron) over the surface (see Figure 2). The trilaminar matrix, as such, may be primarily a convenient interfacial barrier to the cell's microenvironment and a bearer of the molecular machines. This model of the real neuronal membrane is doubtless oversimplified.

Delbrück (this volume), a leader in molecular genetics for a generation, considers that the present state of knowledge of membranes resembles that of chromosome organization 30 years ago, and he predicts that discoveries of membrane organization will rank with the greatest in molecular biology. It is from such a viewpoint that the membrane section of the symposium is here surveyed.

Should neuroscientists, like molecular geneticists of two decades ago, seek a macromolecular type that performs specialized functions by virtue of particular composition and structure? Do we seek enzymes and other substances which carry out topochemical reactions that integrate and "cyberneticize" membrane functions, and do we relate these to vital processes in the cell center and in the cellular microenvironment? Do allosteric interactions between membrane subunits and enzyme assemblies play an important role in this integration? From our knowledge of other membranes, especially those of mitochondria, can we pose productive technical and conceptual strategies for investigating the membranes of neurons and glial cells?

THE MEMBRANE MATRIX The molecular organization of the membrane matrix is fruitfully studied crystallographically in nerve myelin. Recently there has been a recrudescence of interest in the investigation of myelin structure with improved X-ray diffraction methods: about 15 orders of the large (approximately 180 Å) repeating period have been recorded (Kirschner and Caspar, 1969; Worthington and Blaurock, 1969), and detailed crystallographic data have been obtained. At the same time, there has been a saltation in our understanding of the protein of myelin, the subunits of which have been isolated in watersoluble form (Folch-Pi and Sherman, 1969; Sherman and

FRANCIS O. SCHMITT Chairman, Neurosciences Research Program, Massachusetts Institute of Technology, Brookline, Massachusetts

FIGURE 1 Diagrammatic representation of membrane structure. Upper figure: Matrix with lipid bilayer, unit membrane structure. Lower figure: "Greater" membrane consisting of lipid-protein matrix (after the Wallach-

Singer model) and glycoprotein coat ("fuzz"), and intercellular microenvironment also containing macromolecules (probably mucopolysaccharides).

Folch-Pi, 1970), and the role of lipid in determining myelin stability has been assessed (O'Brien, 1965; O'Brien and Sampson, 1965).

A point of major interest is whether the current analyses, as did those of the early studies (Schmitt et al., 1941), require the assumption of continuous lipid bilayers. It seems improbable that the data could be adapted to models that depict the membrane as composed of protein subunits with lipid molecules inserted in molecular folds and oriented in a relatively unspecified manner, although such a structure may exist in the mitochondrial membrane for which the model was devised (Green and MacLennan, 1969). In some membranes, cooperative allosteric interaction may occur between protein molecules capable of transition between two stable states, as suggested by Changeux et al. (1967; Changeux, 1969).

Optical rotatory dispersion and circular dichroism data have been interpreted to indicate that protein in the membrane matrix structure interacts with lipid not through electrostatic bonds, as held in the conventional trilaminar theory, but rather by hydrophobic interaction of protein chains extending throughout the thickness of the membrane. In this view, the lipid does not form a continuous bilayer (see Schmitt and Samson, 1969). The consensus of the symposium participants was that the theoretical basis for any of these models is not rigorous and that lipid bilayers, at least in portions of the membrane, are not excluded by the evidence.

The preparation of a variety of specially designed electron spin labels offers much hope for our gaining important information about the fluidity of membrane matrix, presumably in the lipid-rich portions. McConnell (this volume) sees the protein and the carbohydrate components as conferring solidity to the matrix, whereas unsaturated lipid chains favor fluidity. Myelin lipids are rich in unsaturated chains, and these may promote chain fluidity (see Luzzati et al., 1969). What protects these unsaturated linkages from auto-oxidation? Can fundamental membrane properties (e.g., maintenance of fluid regions that permit transmembrane penetration of carriers) be controlled by alteration of the state of oxidation of lipid double bonds? Whether blisters seen in electron micrographs of freeze-etched preparations indicate regions of fluidity in membrane matrix is not yet certain; electron microscopists tend to associate such regions with processes of endocytosis or exocytosis.

Experiments on various types of membrane models, as described by Delbrück (this volume) and Eigen (this volume), will doubtless provide important new insights into membrane structure and dynamics, particularly when kinetic aspects are investigated by fast relaxation methods and applied to bilayer and vesicular models (Eigen, 1968; Eigen and De Maeyer, 1970).

MEMBRANE-MOUNTED MOLECULAR MACHINES AS SPE-CIFIC ION CARRIERS The mechanism by which cells, especially neurons, distinguish Na⁺ from K⁺ has eluded cell physiologists for generations. The conventional notion that ions are transported through the membrane by ion-specific "channels" explains little at the molecular level, although Onsager (personal communication) expressed the opinion that channels formed by specific chemical groupings (e.g., protein side-chains) of membrane molecules may suffice for ion-specific transport. The concept of polypeptide cages, highly specific with respect to the ions that they enfold and carry across the cell membrane, bids fair to solve this ageold problem. It is as if the "channel" (peptide cage) itself moves across the membrane with its specific ion cargo.

The picture conveyed in the recent work on bilayer models (Tosteson, 1969; Eigen and De Maeyer, 1970) is illustrated in Figure 3. The cation is stripped of its solvate water molecules seriatim, one by one, as the ion enters the carrier cage and bonds coordinately with oxygen atoms of the cage. A conformational shift causes the cage to close. The side chains of the peptide cage are directed outward and, being hydrophobic, minimize interaction with lipid and facilitate transport of the peptide-enclosed ion through the membrane. In lipid bilayer model systems, the addition of certain peptides and antibiotics changes the electrical resistance of the bilayer by orders of magnitude and does so specifically with respect to particular ions, e.g., Na⁺, K⁺, Ca²⁺, and Mg²⁺.

Whether such small-molecule carriers actually exist in brain-cell membranes is unknown, and it will be difficult to isolate and chemically characterize carriers because they are probably present in the membrane in very low concentrations—perhaps one part per million. Eigen (this volume) suggests that the carrier function may be borne in cells by a small molecule linked with an allosteric pump protein, by conformational changes of a specific membrane protein, or by other membrane constituents. The energy source and the coupling for this transport are unknown. The possibility was posed that, by recycling, the carrier might make round trips across the membrane with sufficient rapidity to account for the data of Hodgkin and Huxley. Eigen suggests that, at least in bilayer model systems, recycling might occur in about one millisecond.

The question was raised at the symposium whether transmitter molecules (e.g., quaternary ammonium compounds) might cross the synaptic membrane by a rapid-transit carrier mechanism. It was not immediately apparent how such an unorthodox view might be tested, nor did participants press for an alternative to the canonical quantalexocytosis hypothesis of transmitter release, discussed in more detail below.

The significance of the Na⁺ pump in determining postsynaptic membrane potentials was emphasized, especially as related to the accumulation of ions in thin dendritic branches in which even moderate activity might substantially change the Na⁺ concentration of the neuroplasm (Carpenter and Alving, 1968; Marmor and Gorman, 1970; Pinsker and Kandel, 1969). It is believed that the frequency of firing in thin C-fibers is limited by the capacity of the Na⁺ pump.

EXCITABLE MEMBRANES The excitable mechanism in neuronal membranes involves molecular devices that are not only sparsely distributed in the membrane (about 10 to 20 per μ^2) and difficult to detect by physical means, but also are fast operating (10-4 seconds and maybe much faster). On the assumption that the process involves change in orientation or conformation of macromolecules or their parts, Schmitt and Schmitt (1940) attempted to discover such changes by use of a highly sensitive method for detecting transient changes in birefringence associated with the action wave. These experiments yielded negative results. Recently, in the laboratories of Keynes (Cohen et al., 1968) and of Tasaki (Tasaki et al., 1968, 1969), positive correlations were found between bioelectrical parameters and changes in birefringence, light scattering, and emission by fluorescent probes; in these experiments the signal-to-noise ratio was

FIGURE 3 Diagrammatic representation of peptide ion carrier to indicate role of change in solvation of ion and in conformation of peptide carrier.

greatly augmented by the use of time-averaging computers. The correlations are well described and evaluated by Keynes (this volume). The small (0.01 to 0.1 per cent) changes of birefringence, light scattering, and fluorescence emission depend on the membrane potential rather than on Na+ conductance, and hence tell little about the molecular mechanism of the action wave. Also, current-dependent changes in light scattering and in fluorescence emission may be referable not to membrane changes, but to changes in external compartments of the neuronal microenvironment. This discouraging conclusion of much brilliant experimental work over many years is tempered by the hope that, as knowledge is accumulated about ion carriers, optical methods may yet be devised for ion-carrier detection and characterization. For example, Frank et al. (1969) found birefringence changes in bilayer systems to which lipidsoluble carrier molecules had been added.

The fast-spike wave is important in conveying information rapidly from one neuron to the next in neural circuits. However, slow-wave processes, particularly in dendrites, may play a significant role in neural transactions and information processing in the brain. Here is an area of great promise for biophysical and biochemical investigation. The problem of the postsynaptic potential, usually explained in terms of Na⁺, K⁺, and Cl⁻ conductances, i.e., the ionic effectors rather than the molecular-reacting system, should be re-examined in the light of recent studies of specific ion carriers and of membrane ultrastructure.

Neuronal junctions

Recent electron-microscope investigations suggest that certain synaptic structures, still poorly characterized, may be functionally important not only in guiding synapse formation in the developing nervous system, but also in controlling the moment-to-moment synaptic activity of the adult nervous system. Also worth noting is the powerful role of scanning techniques, clearly indicated in the work of Lewis et al. (1969), which show details of synaptic connectivity.

The end bulb, cleft, and postsynaptic tissue possess a rich ultrastructure. More is involved than vesicles and membranes whose variations of polarization underlie impulse transmission in neuronal circuits. The end bulb is full of equipment, and there is what may be called a "synaptic apparatus" that may provide a degree of continuity between presynaptic and postsynaptic junctions across the cleft. The term "synaptic apparatus" is here used to denote a proteinaceous structure, including presynaptic dense projections, cleft structure, and subsynaptic web. THE SYNAPTIC APPARATUS From the plenary lectures of Robertson (this volume) and of Bloom (this volume), as well as from descriptions by Akert (Pfenninger et al., 1969; Akert and Pfenninger, 1970; Bloom et al., 1970), we learn that a synaptic apparatus exists which, to judge from its staining properties, may extend from far inside the presynaptic terminal to deep within the postsynaptic neuroplasm and may occur in brain synapses in a wide spectrum of animal forms. The nature of the cleft-material, which is more difficult to preserve, remains conjectural.

Little is known about the chemical nature or function of the synaptic apparatus. In all probability, it is proteinaceous and contains basic groups that stain with ethanolic phosphotungstic acid and bismuth iodide (BiI₄). Zinc iodide (ZnI) apparently complexes with osmium tetroxide (OsO₄) inside vesicles.

Perhaps, as in the case of the mitotic apparatus, it will be possible, through the development of special methods, to isolate the synaptic apparatus, to characterize the protein, and to deduce the function of the apparatus. The amount and the organization of the synaptic apparatus increase with development until, in maturity, a complex structure is formed that consists of dense projections extending from the presynaptic membrane well inside the terminal; a hexagonal, weblike plaque facing the presynaptic membrane; and a fibrous web penetrating into the postysnaptic cytoplasm. Some of the properties suggest the presence of elongate (protein?) macromolecules or filaments parallel to the axis of the synaptic apparatus and normal to synaptic membranes.

The trilaminar membranes limiting the presynaptic and the postsynaptic structures are readily distinguishable from the synaptic apparatus, but it is possible that, at particular regions, the membranes are pierced by the fibrous synaptic apparatus. Preliminary experiments described by Akert (see Bloom et al., 1970) suggest that Ca^{2+} may be important in binding presynaptic and postsynaptic membranes and that this binding is reduced by the high ionic strength of the extraction medium.

The intercellular cleft, considered by physiologists primarily as a medium for the diffusion of transmitter, is shown by special techniques to contain a substantial complement of macromolecular material, including glycoprotein, glycolipid, and perhaps mucopolysaccharide. According to Bogoch (1965, 1968, 1969) and Barondes (1969a, 1969b, this volume), this material commonly found in intercellular space and in the microenvironment of neurons may provide specificity and molecular recognition important in the ontogenetically correct linking of neurons and perhaps in the consolidation of experiential information. Examples of molecular surface recognition in various cell types are well known. An impressive example is the specification of pathways for the homing of lymphocytes in the vascular-lymphatic system; alteration of the terminal groups of the carbohydrate chains by treatment with glycosyl or fucosyl transferases changes the pattern of the lymphocyte homing (Gesner and Ginsburg, 1964).

Barondes (1968) found that a portion of the protein synthesized in the soma and transported down the axon is conjugated with carbohydrate moities in the synaptic terminal; the glycoprotein thus formed presumably passes through the synaptic membrane and becomes part of the surface of the presynaptic membrane or is contained in the intercellular cleft material. In the view of Bogoch (1968; personal communication), alteration of carbohydrate (glycoprotein) end groups is a fast topochemical enzymatic reaction that plays a central role in molecular specification of synaptic function, hence also in phenomena such as information processing and memory consolidation.

The synaptic cleft may be the locus of a kind of valving of synaptic function through intrusion of glial membranes and processes into the space (see Bunge, this volume).

Synaptic receptors for biodynamically active substances such as transmitters, hormones, and perhaps certain trophic substances represent a fascinating and important subject for molecular neurobiological investigation. Receptors are usually pictured as being macromolecular, probably protein in nature, and situated on the cleft surface of the postsynaptic membrane. Two strategies of research have been considered to characterize receptors:

1. Affinity labeling, in which the molecular topography of the receptor is deduced from molecular parameters of substances able, in varying degrees, to bind to the receptor and to elicit the appropriate physiological response. This type of investigation is being employed profitably by Karlin (1969).

2. Direct isolation of receptor molecules, in the manner effectively demonstrated by Gilbert (this volume) for genetic repressors. Such a possibility, still little explored, is mentioned by Shooter (this volume).

The membrane-bound enzyme adenyl cyclase is thought to be in close interaction with receptors and to be allosterically activated by them (Figure 4). This enzyme converts ATP to cyclic adenosine monophosphate (AMP), a nucleotide containing energy (of hydrolysis) greater than that of ATP (Greengard et al., 1969). Cyclic AMP appears to be a common effector in cells, a second messenger, bringing about results usually attributed to hormones or other highly biodynamic substances, including synaptic and neuromuscular transmitters. The investigation of the biological and biochemical role of cyclic AMP and adenyl cyclase has expanded rapidly in the last few years. Its role in brain-cell function was the subject of a recent Work Session of the Neurosciences Research Program (see Rall and Gilman, 1970). Bloom and his colleagues (Siggins et al., 1969; Bloom, this volume) have discovered important facts about

FIGURE 4 Diagrammatic representation of the role of membrane-bound adenyl cyclase in the postulated linkage between transmitter and intracellular effector (3', 5', cyclic AMP).

the regulatory role of cyclic AMP in cerebellar function and have also demonstrated an antagonistic effect of prostaglandin on norepinephrine action on Purkinje cells.

TRANSFER OF BIODYNAMIC MOLECULES AT THE SYN-APSE; TRANSMITTER DYNAMICS The synapse-once it is formed developmentally-carries out a number of information-processing functions (see Bloom et al., 1970), one of which is transferring excitation across junctions through release by the action wave of a chemical transmitter. The transmitter diffuses rapidly across a 200-Å strait of "saline" and activates receptors, which, in turn, mediate Na+ or Clpermeation and cause excitation (depolarization) or inhibition (hyperpolarization). Another part of the dogma is that vesicles, acting as storage repositories and capable of moving, by yet unspecified means, to the synaptic membrane, discharge their quantal contents of transmitter into the cleft by a process of exocytosis. Certain aspects of this simplistic, canonical view of synaptic function were questioned during the symposium in the light of new facts discovered in recent pharmacological and biochemical investigations; new and interesting alternatives were suggested.

Only a small fraction of brain synapses has been clearly specified with respect to the transmitter involved. It is possible that, in addition to at least five transmitters known to satisfy rigorous criteria, many other putative transmitters may exist. In the usual view, specificity of the transmission is determined primarily by the receptor apparatus rather than by the transmitter. In some synapses (e.g., *Aplysia*) both excitation and inhibition may be mediated (Wachtel and Kandel, 1967).

The quantal hypothesis that Katz (Castillo and Katz, 1956; Katz, 1965) proposed for the nerve-muscle junction has not been definitively proved to apply to cortical synapses; the role of bioelectrical factors in effecting the release, presumably by exocytosis, of transmitter from presynaptic vesicles, is far from clear. Spike waves are not required for release, nor is Na⁺ ion conductance (Moore and Narahashi, 1967); reduction of membrane potential by as little as 6 millivolts, in the case of amacrine cells, may liberate transmitters (Rall, this volume). Other dissident facts have often been quoted: cases in which vesicles are on the "wrong" side of a junction physiologically, are on both sides of a junction, or are in electrotonic junctions at which function presumably requires no transmitter.

Interest centered particularly on release mechanisms. It seems clear that, even according to the exocytosis hypothesis, the vesicle, in emptying its contents into the synaptic cleft, does not fuse the lipid and the protein of its wall with those of the presynaptic membrane. Whittaker (this volume) found that the chemical compositions of the two membranes differ; they are immunochemically distinguishable; moreover, extensive stimulation does not exhaust, or even demonstrably reduce, the number of vesicles, as attested by electron microscopy (see Bloom, this volume; Kety, this volume). No evidence was found at the electronmicroscope level for the view that vesicles move to, and touch, the presynaptic membrane to discharge transmitter (see Gray, 1966). The observation of "blisters" in freezeetched preparations suggested that the transmitter may be liberated laterally from the end bulb rather than at the region of synaptic adhesion (see also Peters and Kaiserman-Abramof, 1969).

Valuable clues to an understanding of the transmitterrelease mechanism, as well as other synaptic functions, come from recent investigations of the release of neurohormones from the neurosecretory cells, of epinephrine and norepinephrine from the chromaffin cells of the adrenal medulla, and of norepinephrine from adrenergic neurons, as in the splenic nerve. The material released resembles in kind and proportion the contents of the vesicle, i.e., transmitter (norepinephrine), protein (chromogranin proteins, dopamine β -hydroxylase), and ATP. These investigations support the exocytosis theory and the notion that, upon excitation, the vesicle at the membrane surface briefly punctures the presynaptic membrane, discharges its soluble content, recedes from the membrane, and re-enacts the cycle of filling with, or synthesizing, transmitter in preparation for another release (see Iversen, this volume). However, Whittaker, in fractionation studies, found transmitter (acetylcholine) not only in the vesicles, but also in solution in the terminal cytoplasm; the evidence indicated that the most recently synthesized transmitter is in the soluble cytoplasmic pool and that it is from this pool that the transmitter is released (see also Robertson, this volume).

As an alternative to the vesicle-exocytosis hypothesis, Kety (this volume) proposes that, although vesicles act as storage receptacles, the presynaptic membrane may also store and release transmitters. K. Rosenheck (personal communication) suggested that not only may the vesicles function as stores for transmitter, but also the soluble proteins may have a specific function in facilitating transmitter movement during stimulation.

Synaptic physiology offers much challenge to the molecular neurobiologist. Not the least of these challenges concerns the transmission from neurons to innervated tissue of substances not involved in transmission of excitation, but required for the specification, differentiation, or maintenance of the innervated cells. These "trophic"—the word is probably as inadequate as the word "transmitter"—substances, as well as the processes by which they are released or delivered from presynaptic endings, remain almost completely unknown (see Guth, 1969).

Discoveries of neuroplasmic flow and fast somatofugal transport of synthesized products to endings relate closely to the problem of the synapse and its possible role in processes other than those of impulse transmission. The fate

and the function of nontransmitter, nonhormonal materials, including mitochondria, which are not consumed en route to the endings but are nevertheless discharged into extraneuronal space at the synapse, are regrettably still unknown, A substantial amount of organic material must be catabolized or otherwise removed. A fraction of this material is protein. Useful clues are furnished by a study of neurosecretion. The peptide hormones pass down the axon in granules that also contain specific proteins, the neurophysins, and ATP. The chromogranins and several other proteins (enzymes) in small quantities accompany catecholamine in dense core vesicles both in the adrenal medulla and in the sympathetic neurons (e.g., splenic and vas deferens), which are the only ones thus far studied. Why the neuronal soma produces protein to accompany catecholamine down the axon remains a mystery, as does the function of the protein liberated at endings in amounts greater than that of transmitter. Why should ATP (present in stoichiometric, 1:4, proportions to catecholamine in the chromaffin granule) presumably, after making the intravesicular journey down the adrenergic axon, be extruded along with transmitter into the synaptic extraneuronal space? Do still-undiscovered, energy-requiring reactions take place there? Are they related to the metabolic maintenance of brain tissue or to still-uncharacterized neurophysiological processes?

Could we be entering a period in which the theoretical basis of neurophysiology may be as thoroughly revised as it was when neurohumoral, rather than bioelectrical, transmission of the impulse was demonstrated to occur at most synapses (see Schmitt and Samson, 1969)? Will macromolecules, proteins (e.g., chromogranins), conjugated proteins, polysaccharides, and enzymes play an important role? Could they, through interaction with transmitters or with synaptic structures, give rise to chemical modulation of function, especially to physiological or psychological plasticity? These possibilities were discussed in some detail at a recent NRP Work Session on Macromolecules in Synaptic Function (Bloom et al., 1970).

Biosynthesis and gene expression in brain cells

Little is known about mechanisms of gene expression specifically relevant to the functioning of neurons and glia (see Ebert, 1967). Processes may take place in eukaryotes, and especially in their nervous tissue, that are markedly different from the prototype that has emerged from a decade of brilliant investigations of prokaryotes. Many new discoveries along this line were brought out in the symposium organized and chaired by Edelman (this volume). Especially interesting to students of plasticity are transcriptional and translational variants that may be especially sensitive to ionic strength, particular ions, and certain biodynamic molecules. Recent experiments indicate that physiological (i.e., electrical or transmitter) stimulation of individual, charted, *Aplysia* ganglion cells increases RNA production that is related to the postsynaptic potential, but not to spikes produced by antidromic invasion (Peterson, 1970; Peterson and Kernell, 1970; Kernell and Peterson, 1970; but see Berry, 1969).

Synthesis of specific proteins such as tyrosine hydroxylase is decreased by the administration of inhibitors of protein synthesis, according to Weiner (personal communication) and Axelrod (see Mueller et al., 1969; Thoenen et al., 1969). Although nothing is yet known about the linkage between membrane and biosynthetic processes, this line of investigation seems very promising (see Bloom et al., 1970). An interesting suggestion made by Weiner (1970) is that inhibitors of protein synthesis that block permanent memory storage may act by blocking the synthesis of enzymes necessary for the synthesis of transmitters, without which synaptic transmission in the relevant circuits would be abolished along with learning and consolidation.

Approaches to the problem of gene expression from the comparative and the evolutionary views may also prove profitable (M. J. Cohen, this volume). For example, electrical depolarization of *Chironomus* gland cells leads to chromosomal puffing, i.e., to greatly accelerated production of RNA; the linkage between bioelectrical and synthetic processes is unknown.

Textbook portrayals of the neuron—usually the vertebrate motor-effector neuron—are probably far from typical; patterns of dendrites, axons, and terminal branchings vary greatly in the central nervous system and in various animal forms. Cohen points out that the pattern of many invertebrate neurons differs importantly from that characteristic of vertebrate neurons in the relative isolation of the soma, which contains the biosynthetic apparatus, from the bioelectrical signal-conducting dendrite and from axonal mechanisms. Correlated with this isolation is the stereotyped behavior of many invertebrates.

Physiological and psychological plasticity apparently require active participation of biosynthetic and metabolic regulatory processes in neurophysiological function. The role of a few "command" neurons (Wiersma and Ikeda, 1964; Kennedy et al., 1969; Wilson, this volume) in invertebrates is substituted in vertebrates by a multiplicity of neurons, highly differentiated in structure and connectivity. Important in the present context, however, is the close linkage between gene expression and bioelectrical parameters. In the study of this linkage in fortunately chosen invertebrate forms (e.g., *Aplysia* and certain insects) lies promise for rewarding molecular neurobiological research. Such work may establish a base line for the investigation of more complex vertebrate neurons capable of plastic alteration subserving learning and memory.

In the broad spectrum of neurochemical research problems, the search for brain-specific macromolecules, particularly proteins, produced by gene expression in brain cells offers much promise. The catalogue of these proteins presently includes the S100, 14-3-2, antigen α , and certain myelin proteins. As more are added to the list, understanding of their localization and specific function will provide important growth points in neurochemistry. Nevertheless, the brain-cell problem is more subtle than that of other tissues (e.g., muscle, which depends for function on relatively high concentrations of effector proteins, actin and myosin). Much more may be involved in brain functioning than is implied in impulse propagation and transmission; processes different from those commonly met in other tissues may be responsible for the storage, retrieval, and psychological utilization of experiential information of the brain.

Equally interesting and profitable, as Shooter (this volume) has ably shown, is the study of the response of brain cells to stimulation or inhibition of gene expression by highly potent biodynamic agents such as hormones (of which insulin provides an excellent investigative model), transmitters (and enzymes necessary for their synthesis), still ill-defined trophic substances, and, most spectacularly, nerve growth factor, the study of which has been brilliantly developed by Levi-Montalcini (see Levi-Montalcini and Angeletti, 1968). From the work of Shooter (this volume) and his colleagues (see A. P. Smith et al., 1969) has come a better understanding of the biochemical characterization of this substance, its constituent subunits, and their role in neurobiological phenomena. Meanwhile, it remains to be definitively demonstrated that nerve-growth-factor action is not an epiphenomenon.

ORGANELLES The study of the specifically neuronal role of mitochondria and other organelles is in an early phase. In brain cells, unlike other tissues, these organelles may travel relatively large distances from cell center to cell periphery at the endings of axons and dendrites. The most obvious purpose of this transport process is to provide ATP energy along the way, to bring metabolites, proteins, specific enzymes (such as transmitter-synthesizing enzymes carried in vesicles), and trophic and other regulatory substances to axonal endings. What becomes of the organelle residues at endings? Are endings graveyards in which organelles, the usefulness of which has ended, are dismembered and disposed of, or does organelle-borne cargo (e.g., enzymes, proteins, ATP) participate in dynamic processes at endings?

Lehninger (this volume) points out that mitochondria provide a valuable model for neuronal membranes with respect to ultrastructure (role of enzyme assemblies, structure proteins, and other machinery), to ion transfer (effects of valinomycin and other carriers), and even to bioelectrical properties. Mitochondria have been impaled by electrodes, and membrane potentials have been measured as a function of the composition of the microenvironment (Tupper and Tedeschi, 1969a, 1969b, 1969c).

Neuroplasmic kinesis

One of the most active areas of molecular neurobiology today and one that brings into full play the wide range of metabolic, biogenetic, and bioelectrical dynamics of neurons is that of neuroplasmic flow and fast transport of neuroplasmic constituents. Although we are still largely ignorant about the nature, fate, and function of the transported material and the mechanism of transport, investigation of this newly opened territory is spurred by the hope of finding experimental answers not only to problems of neuronal dynamics already posed, but to the possibility that the problem of memory and learning may also be illuminated. The major issues are discussed by Weiss (this volume, Chapter 6), who first opened up the field experimentally, and Davison (this volume) provides a critical evaluation of theories of mechanism of flow and transport. It remains but to mention certain points raised at the symposium and to indicate my own views regarding some of the issues.

Cytoplasmic flow and fast specific transport are apparently ubiquitous in neurons and probably in many other types of cells, but the phenomenology varies over a wide range of cell types, depending on their specialized function. Similarly, the ultrastructural factors, e.g., ratio of microtubules to neurofilaments and the presence of vesicles and mitochondria, may vary widely. Therefore, Weiss's caution against premature attempts at explanations and generalizations is warranted.

It seems probable, as Weiss long ago proposed, that slow (about 1 mm per day) flow is a mass movement of viscid, semisolid neuroplasm generated by mechanisms that remain turned on genetically perhaps throughout the life of the neuron. A possible explanation of this flow is Weiss's suggestion of peristaltic contraction of membranes-neuronal, glial, or both in combination. No specific biophysical or biochemical mechanism for the peristalsis has, however, yet been provided. Membranous systems (e.g., mitochondria and certain kinds of vacuoles) may contract. The axon-Schwann cell interface is in some cases (as in some crustacean and molluscan axons) highly, although irregularly, serrated, mitochondria being concentrated at the interface and oriented with respect to the inpocketings of the serrations, as though energy were required for local processes (see Geren and Schmitt, 1954, 1955). This may be a reflection of peristalsis-like contraction.

Peristaltic contractions that move constituents by hydrostatic pressure, whether at the cellular or organelle level, cannot explain fast transport or other properties of cytoplasmic flow that move particulates, such as dense-core vesicles, specifically with respect to other neuroplasmic components, such as microtubules and neurofilaments. Present evidence favors the view that mechanisms underlying the slow bulk flow differ from those producing fast transport of particular materials, such as transmitter-containing, dense-core vesicles in adrenergic neurons. Velocities of fast transport range from about 20 to 2000 mm per day; different axon types manifest different velocities, as, for example, various kinds of striated and smooth muscles show different contraction velocities and frequencies.

Materials most rapidly transported seem to be packaged in particulate, vesicular form (neurosecretory granules, dense-core vesicles, lysosomes). As in fast transport in other cell types, including movement of chromosomes, pigment granules, and various kinds of vesicles, so in neurons the transport occurs in close association with microtubules. The evidence is admittedly circumstantial, but it is parsimonious to assume that microtubules are essential in the transport process and perhaps act as directional guides and possibly as energizing substrates for the transport of vesicles and membrane-bound particulates.

In a speculative model, along the lines of modern muscle theory, I have postulated (Schmitt, 1968; Schmitt and Samson, 1968) that chemomechanical energy coupling takes place between subunits of the microtubules and those of the vesicle surface membrane: a sliding or saltating vesicle theory is suggested, analogous to the sliding filament theory of muscle contraction (Huxley, 1969). Some evidence has been adduced to support this hypothesis. Recently D. S. Smith et al. (1970) have obtained electron micrographs of unmyelinated axons and synapses in the central nervous system of lamprey (Petromyzon marinus) ammocoetes. They reveal almost diagrammatic clustering of vesicles around microtubules. It remains to be seen whether such instances represent isolated cases with no general significance or whether clustering is widespread, but, as do microtubules themselves, requires special preparative techniques for preservation and visualization in the electron microscope. The momentary contact between vesicles and microtubules during the postulated saltation might be highly metastable and difficult to preserve and demonstrate in that microscope.

The protein of brain microtubules, present in substantial amounts in developing neurons (Dutton and Barondes, 1969), has been obtained in purity (Marantz and Shelanski, 1970), and vesicles have been isolated from nerve tissue by various workers. Therefore, simple systems containing microtubules and vesicles can now be investigated and a model for saltatory transport can be developed. For example, supercontraction of purified actomyosin was used by Szent-Györgyi as a model for muscle contraction, and the addition of ATP to glycerinated preparations (muscle, dividing cells, ciliated cells, and so forth) permitted investigation of details of contractile mechanisms.

Because of the relation between microtubules and neurofibrils (see Schmitt and Samson, 1968) and because microtubules may reveal transport routes in the perikarya, dendrites, and axons of neurons, the descriptions of neurofibrils in the classical neurohistological and neurophysiological literature may suggest functional significance.

The directional transport of materials in cells by vesicles or particulates may, in evolution, possibly antedate muscle as a means of chemomechanical energy coupling to transport protoplasmic components. Transport was readily demonstrable and measurable in neurons because their elongated axons greatly facilitate testing with radioactive and fluorescent tracers. Clearly the investigation of transport in neuroplasm ranks high in the list of priorities for molecular neurobiologists and may have general biological significance.

Summary

The symposium demonstrated that, among the neurosciences, molecular neurobiology is in a fruitful period, not only in re-examining time-honored tenets in the light of modern molecular biological concepts and techniques, but also in perceiving opportunities for new neurophysiological and electron-microscopic discoveries. Significant advances have been made since the 1966 NRP Intensive Study Program.

Axoplasmic movement and fast transport have been examined in many neuron types, the parameters governing the phenomena have been better defined, and progress has been made in understanding physicochemical mechanisms. The study of trophic effects on innervated tissue has benefited from this upsurge of activity, although little is yet known about the identity of trophic substances—other than acetylcholine—and the mechanism of transfer from presynaptic to postsynaptic structure.

Synapse study is in active ferment: new discoveries have been made of ultrastructure and of the neurochemistry of synaptosomes and other particulates isolated after fragmentation; new data have been obtained on the mechanism of release of transmitter and the possible information processing of macromolecules in synaptic function. The interposition of adenyl cyclase into the receptor-effector train via cylic AMP suggests that a substantial revision of views tacitly accepted by neurophysiologists during the last two decades may be imminent.

Membrane neurobiology has been greatly stimulated by widespread studies of membrane structure and properties in general, of lipid bilayers with and without activating additives, and by new concepts of specific transport of ions through membranes.

Little has been learned about the molecular or ultrastructural mechanisms involved in distributed, parallelprocessing, holistic activity of the brain, which is thought by some investigators to occur with the neurophysiologically more conventional connectionistic processing of experiential information in learning, memory, and other brain processes (see Nelson, 1967; this volume). Attention has been called to the outer surface of brain-cell membranes and to macromolecular (polysaccharide, glycoprotein, and glycolipid) constituents of intercellular space-a continuous, interconnecting compartment throughout the brain-as a possible substratum for such phenomena. However, other than changes in impedance and slow potentials (Adey, 1969), little has yet been adduced to explain these central phenomena of brain function. This situation is understandable; the reductionist, physicochemical approach requires that the higher-level phenomena be reasonably well characterized before mechanisms can be deduced effectively.

Lessons learned from the evolution of genetic theory can be profitably applied to problems of brain function (Schmitt, 1965) whether or not molecular coding proves a primary process in the latter as in the former. Developmental and genetic biologists of the 1920s and 1930s-the elite of those days-were sure that key clues to the bewilderingly complex phenomenology of genetics and development must be sought at the cellular or higher-systems level. To be sure, the ground rules of this important segment of life science had to be established at the cellular and organismic level, but the conceptual breakthrough came from a combination of finding the simplest systems (microorganisms and viruses) that displayed the phenomena and of discovering the macromolecules (DNA and RNA), their structure, and chemodynamic properties that subserve the genetic process.

Is any particular macromolecular type likely to prove as important a key to unlock the mysteries of brain function as it was in the case of genetics? Interestingly, molecular biologists—the elite of our day—also seem certain that the key to brain function is to be sought at the cellular or higher-systems levels. The ground rules in the brain sciences, comparable with those of genetics of the mid-twentieth century, have not yet been deduced. Much, however, has been learned in recent years about the properties of macromolecules and their complexes and of fast reactions that may govern macromolecular interaction; these may well prove relevant to major brain problems.

Many workers from other fields the world over are joining the ranks of investigators of neuroscience. The intellectual atmosphere today contains the distinct intimation of great discoveries of utmost importance to man—the functioning of his own brain and the nature of his being. To realize the potential of neuroscience requires not only concentration on particular levels—molecular, cellular, neural, or behavioral—but, importantly, on a mutual sharing of the precepts and conceptual insights of scientists of demonstrated originality at each level, under conditions that foster intellectual and conceptual "allosterism." This is the *raison d'être* of the Neurosciences Research Program.

Acknowledgments

The author gratefully acknowledges the invaluable aid of Drs. F. E. Samson, P. G. Nelson, B. H. Smith, J. H. Bigelow, H. H. Wang, and L. N. Irwin in interpreting, collating, and integrating information communicated during the symposium on Molecular Neurobiology.

This work was supported by grants from the United States Public Health Service, National Institutes of Health (GM10211), National Aeronautics and Space Administration (Nsg 462), the Rogosin Foundation, and the Neurosciences Research Foundation.

RECOGNITION AND CONTROL AT THE MOLECULAR LEVEL

The Kendrew model of a three-dimensional structure of ribonuclease-S was made available through the courtesy of Frederic M. Richards, whose chapter begins on page 901. The path of the backbone of the polypeptide chain is shown by the dark tubing. The strong, specific interaction whereby the enzyme binds 3' pyrimidine nucleotides at its active site is a clear example of molecular recognition. Chapter 77 EDELMAN 883

Prefatory Comments on Recognition and Control at the Molecular Level

G. M. EDELMAN

SOME JUSTIFICATION, BUT NO APOLOGY, must be made for the fact that this symposium does not include a single paper explicitly concerned with the neurosciences. One of the major accomplishments of the last ISP was to dispel naive expectations that the nervous system worked by encoding information about the world directly into macromolecules. Nonetheless, a detailed understanding of the workings of the nervous system will obviously depend on a knowledge of the structure, function, and interaction of specific proteins, nucleic acids, and small molecules. Only beginnings have been made in isolating and determining the function of specific neural proteins, and the role of protein synthesis in neuronal behavior is not yet understood. Moreover, much remains to be understood about simpler systems before an attempt can be made to apply our knowledge of molecular biology successfully to the more complicated problems of the nervous system.

This symposium on recognition and control at the molecular level was planned, therefore, with two major purposes in mind. The first was to provide neuroscientists with some views of the relation between the structure and function of proteins and nucleic acids, particularly in terms of problems of gene expression. The second was to emphasize recent explorations into the properties of DNA and special pro-

G. M. EDELMAN The Rockefeller University, New York, New York
tein systems in eukaryotic organisms, because the nervous system has evolved in eukaryotes.

There is sufficient justification for considering the molecular genetics of eukaryotes as a subject in itself. Recent investigations of a number of systems in eukaryotes suggest that other modes of control may be operative in addition to those described for micro-organisms. There are a number of phenomena in eukaryotes that may provide clues to the evolution and workings of complex systems of differentiation. They include: (1) multiple copies of genes and the occurrence of differential gene amplification; (2) chromosome diminution and elimination; (3) systems of metastable and transposable control elements at the chromosomal level, such as those found in maize; and (4) allelic exclusion and evidence for translocation of DNA in the biosynthesis of immunoglobulins. The immune response represents a selective system that has evolved to contend with unexpected molecular interactions. Although none of the detailed mechanisms of the immune response may have correlates in nervous tissue, the concepts developed to analyze immunity at the molecular level will be useful in molecular neurobiology.

The list of phenomena I have mentioned could be extended but, even so, it might be considered a collection of evolutionary curiosities and byways without general significance. It may be more valuable, however, to consider these phenomena as suggestive of the idea that control over differentiation and specific protein synthesis in eukaryotes requires mechanisms *additional* to those described for prokaryotes.

With these phenomena in mind, we may ask a number of questions about levels of control in gene expression. It is clear from the work of Jacob and Monod that protein repressors function as negative control elements for specific operons. Searching efforts are being made to determine whether detailed systems of translational control exist. The intriguing new possibilities are that replication of portions of the eukaryotic genome, as well as somatic recombination and transposition of DNA, may also serve as mechanisms in the control of gene expression. The stability and reversibility of such processes and their direct roles in cellular differentiation are being examined. The classic idea of constancy of the DNA in somatic cells must be reconsidered in terms of the precision of the measurements as well as the relatively small proportion of the genome that must be affected to exert a large change in gene expression. It is pertinent to ask whether the existence of multiple copies of genes in the eukaryotic genome is a *fundamental* development in evolution. Not only could it change the over-all amounts of synthesis of tRNA or messenger RNA, but it might provide preadapted pools of genetic information which could respond to unexpected selective pressures during evolution. In this sense, the existence of multiple copies of genes may change the rate of evolution and may have been one of the chief reasons for the evolution of the complex chromosomes of eukaryotes.

Characteristically, molecular biologists will go to any species for an answer, because of their belief that there is a general pattern in the fundamental processes of all organisms. For that reason, this symposium was also designed to review and extend our knowledge of the control of gene expression in prokaryotes. Here we are on more solid ground, although there are still many unsolved questions. Molecular interactions of DNA and repressors, as well as the mechanisms of recombination and replication in phage and bacteria, are currently under active study. Such processes also occur in eukaryotes and undoubtedly they will bear resemblances to their counterparts in prokaryotes.

Ultimately, these processes must be understood in terms of detailed chemical interaction of specific macromolecules. The papers in this symposium were arranged to proceed from the primary and tertiary structure of proteins and protein-small molecule interactions, through the intricacies of protein-nucleotide interactions required in protein synthesis on the ribosome, and, finally, to a consideration of immense structures, such as the chromosomes themselves.

Such a program sounds overambitious when dissected out of the particular fabric made up of the following series of papers. Clearly, many details have been given inadequate coverage, and no attempt to be inclusive could possibly succeed. The main hope, however, is to reveal the molecular biological approach to several current problems. At least some of these problems have a direct bearing on neurobiology, and all of them will eventually bear in one way or another on the analysis of the development and functioning of nervous tissues.

8 The Structure and Genetics of Antibodies

G. M. EDELMAN

THE VERY EXISTENCE of brains capable of learning indicates that certain biological systems can deal with enormous amounts of information without proportionately great increases in the amount of genetic material. Systems such as the primate brain can cope with unexpected constellations of events, all the information for which certainly could not have been incorporated in a prior genetic program. At the present stage of our knowledge, we do not know how the nervous system accomplishes such a feat, but examination of simpler systems capable of dealing with information that the organism has not seen either in its somatic lifetime or in the history of its evolution may give us a few clues.

Perhaps the most extensively analyzed example of such a system is the adaptive immune response, which is found only in vertebrate species. (For a brief review, the reader can consult Nossal, 1967; Edelman, 1967; and Jerne, 1967). Consideration of the special characteristics of the antibody response leads to some general conclusions about the nature of biological systems that can contend with unexpected events. In addition, it suggests that unusual genetic mechanisms have evolved to deal with such events. The production of antibodies by plasma cells is an example of a system of differentiation in eukaryotic organisms that requires molecular control mechanisms in addition to those that have been so well studied in bacteriophage and bacteria. We can hardly say that the immune system provides anything more than a provocative example, however, for none of the detailed genetic mechanisms have been worked out.

Nevertheless, there are other reasons for beginning this section on recognition and interaction at the molecular level with a discussion of antibodies. First, antibodies represent the only well-studied case of a molecular recognition system with selective properties, and there are reasons to expect that other examples will be discovered, particularly in the nervous system. Second, the analysis of their primary structures and the thermodynamics of antigen binding indicate that antibodies are as good an example of protein specificity as can be found. Third, there is evidence to indicate that antibodies, which are very large protein molecules, have evolved by mechanisms of gene duplication that may be more general than had been previously suspected from the results of analyses of smaller protein molecules, such as ribonuclease and lysozyme. A consideration of antibody structure thus leads naturally into discussions of the problem of multiple genes in eukaryotic organisms.

The specific aim of the present paper is to review certain features of the immune response in terms of knowledge of the chemistry, genetics, and evolution of antibodies, particularly the prevalent class of mammalian antibodies known as γG immunoglobulins. An attempt is also made to relate recent findings on the chemistry of antibodies to other more general problems of protein structure and differentiation.

The sequence of events in humoral antibody production

Several detailed studies have been made of the kinetics and heterogeneity of humoral antibody production after the administration of antigens. Classical studies of the immune response have shown that introduction of an antigenic molecule into vertebrate organisms elicits the synthesis of antibodies that can bind specifically to that antigen (Landsteiner, 1945). Different systems differ in detail, but the set of studies (Uhr, 1964) schematized in Figure 1 will serve as an example.

Following the injection of antigen and after a variable latent period, antibody activity rises exponentially in the serum for four to five days. The first antibody molecules to appear belong to the γM globulins, which have a sedimentation coefficient of 19S and a molecular weight of about 10⁶. Synthesis continues at a diminishing rate for another four to six days, and then the level of γM antibodies falls with a half-life of 24 hours.

About one week after the initial injection, there follows an exponential increase of 7S antibodies of the γ G immunoglobulin class (molecular weight 150,000), which lasts for about four days. Synthesis of γ G immunoglobulin may continue thereafter at lower rates for periods ranging from two years to the entire life span of the animal.

One month after the first injection, when the primary 7S response has reached a plateau, a second injection of antigen yields a *secondary response*, consisting of an accelerated increase in γG immunoglobulin production. Although a secondary response is not seen in γM antibody production, a second dose of antigen nine days after the first (when γM

G. M. EDELMAN The Rockefeller University, New York, New York

FIGURE 1 Sequence of antibody responses to two injections of antigen (Ag) spaced about three weeks apart. The antibody level is measured in the serum of the animal, and synthesis of two classes of immunoglobulin is stimulated: γM immunoglobulin and γG immunoglobulin. The second antigenic stimulus provokes an accelerated and increased production of specific γG immunoglobulins. This is known as the specific anamnestic response, or immunological memory.

antibody production has ceased) results in the production of another peak of synthesis, which suggests that the γM response depends on continued presence of the antigen at a level higher than that required for γG antibody synthesis.

The major point to emphasize here is that, regardless of their class, the antibodies are capable of binding to the injected antigen but not to chemically unrelated antigens. Moreover, there appears to be a real synthesis by antibodyforming cells, not just a release from some store. Upon a second encounter with the same antigen, the system shows "immunological memory," i.e., the response is more rapid and larger amounts of antibodies specific for that antigen are synthesized. Thus, antibodies constitute a molecular recognition system that is remarkable for its specificity, range of response, and control.

Specificity and range in antigen binding: complementarity and degeneracy

The variety of chemically different antigenic structures is enormous: antibodies may be produced by the injection of protein, carbohydrate, nucleic acid, or artificial antigens known as haptens. The capacity of the immune system to respond to so wide a range of stereochemically distinct molecules is as astonishing as the specificity with which each antigen is bound. In the past, many immunologists (see Karush, 1962) were preoccupied with analyzing the thermodynamics and mechanisms of antigen binding by antibody molecules. From their studies, it is clear that the

FIGURE 2 Diagram of the complementarity between antibody and hapten antigen (the dinitrophenyl group) coupled to a protein carrier. The various contours of the antibody active site indicate the greater or lesser degrees of fit between sites of *different* antibody molecules and the same antigen.

binding depends on the close complementarity of the shapes of the antigen and the antigen-binding site on the antibody molecule. This complementarity (Figure 2) has been deduced from studies of cross reactions (Landsteiner, 1945) and the nature of the binding: the free energy ranges from approximately -4 to -12 kcal/mole, and hydrophobic interactions, hydrogen bonds, electrostatic interactions, and steric repulsion contribute in varying degrees, depending on the particular antigen-antibody reaction. Because this type of binding does not differ from that between enzymes and substrates, it is tempting to think of antibodies in the same way as one thinks of enzymes.

There are, however, several features of the immune response that indicate that this analogy holds only in the most superficial sense. For example, unlike most substrates for enzymes, antigens that never existed during the evolutionary history of the organism may be synthesized (Landsteiner, 1945). Moreover, antibodies may be elicited by virtually any protein molecule from a variety of animal species. It is unlikely that all these proteins played a direct role in natural selection during the evolution of the immune response in each vertebrate species. Furthermore, unlike the induction of enzymes by substrates, a single antigen usually elicits the synthesis of a large population of different antibody molecules that, with greater or lesser degrees of complementarity, fit the antigen (Fahey, 1962; Haber, 1968). Thus, the antibody response is degenerate, i.e., there is a many-one relationship between antibodies and any single antigen, and no single "best" antibody has evolved for each particular three-dimensional antigenic structure. This heterogeneity of antibodies is one of the most important features of the immune response, and the analysis of its structural basis and biosynthetic origins leads directly to several of the most fundamental problems of immunology.

The idea of selection

Early attempts to explain antibody synthesis resulted in the formulation of a number of so-called instructive theories (Breinl and Haurowitz, 1930; Mudd, 1932; Pauling, 1940). The fundamental notion underlying these theories was that information on the three-dimensional structure of the antigen was necessary at some stage of the synthesis and folding of the polypeptide chains of the antibody molecule. In their simplest forms (Pauling, 1940), instructive theories suggested that the antigen served as a template around which was folded that portion of the antibody polypeptide chain destined to become the antigen-binding site (see Figure 2).

Instructive theories have now been abandoned (Haurowitz, 1967), largely because the results of analyses of the structure of antibody molecules and the cellular dynamics of the immune response have made them untenable. They have been supplanted by selective theories (Jerne, 1955; Burnet, 1959; Lederberg, 1959), which state that the information required for specificity and range *already* resides in the organism before exposure to the antigen. The antigen serves to stimulate (or select) only those cells that synthesize complementary antibodies. As shown in Figure 3, selective theories require a minimum of three conditions: (1) the organism must contain information for the synthesis of an *enormous* repertoire of different antigen-binding sites, most of which may never be used; (2) there must be a mechanism for antigen trapping to favor encounter with the appropriate lymphoid cells; and (3) stimulated lymphoid cells must constitute an amplifier of high gain, which is triggered by the antigen, so that, after selection of the appropriate cells, a significant number of antibody molecules of the correct specificity are produced. This is realized by cell division and an increased rate of antibody synthesis in the progeny cells.

Such a system has a number of interesting properties. It is clear, for example, that the specificity of the antigen-binding function (ABF) is a property of the entire system rather than of single antibody molecules. Moreover, the system is clonal, i.e., each cell synthesizes a single variety of antibody molecule and, after encounter with the appropriate complementary antigen, is stimulated to divide and form progeny cells, which synthesize the identical type of antibody at greatly increased rates (Mäkelä, 1967). The released antibodies can bind antigen in the fluid spaces of the organism or bind to cells, and they can also carry out a number of effector functions (EF) which do not depend on the specificity of antigen binding. These include complement fixation, skin fixation, opsonization, and placental transfer (Cohen and Porter, 1964). Effector functions are, in one sense, the important functions of antibodies, for they carry out the major tasks of the immune system. Nevertheless, it is the binding or recognition function that is of more fundamental concern to us here, for it appears to have evolved in an unusual way. One additional set of hypothetical functions could be classified as effector functions, and are of fundamental interest because they may be absolutely required to permit the selective system to operate: particular structures on antibody molecules may serve to trigger mitogenesis and cell maturation after interaction with the antigen. Similar or identical structures on antibodies may also serve to block these essential steps and lead to a specific failure to respond to a particular antigen, a state known as

FIGURE 3 A scheme of events in a selective antibody response. The letter n inside stem cells indicates that they are uncommitted and pluripotential. For clarity, diversification and commitment are presented as separate events, although a detailed model of differentiation from various stem cells is not intended. Different Arabic numbers outside each cell represent unique immunoglobulins produced after clonal commitment. These "receptor" antibodies can interact with various antigenic determinants. The degeneracy of the immune response is indicated by the recognition of a single antigenic determinant (e.g., A or B) by several different cells, each producing different antibodies which more or less fit (see Figure 2). Interaction between a committed cell and antigen stimulates amplification, which consists of maturation, mitosis, and increased antibody synthesis.

immune tolerance. So far, however, these structures have not been identified.

Although this picture of a selective molecular recognition system is qualitatively satisfactory, we lack detailed quantitative information on many of its features, and we are far from a complete quantitative description of the immune response. We do not know the number of different antibody specificities in an organism, the mechanism of their generation, the efficiency of the processes of diversification, trapping, and amplification, or the features of control required to allow the whole system to function (Möller, 1967). One of the least-understood features of the system is the rate at which the various lymphoid cells encounter the antigen and each other. Moreover, very little is known of the chemical state of the antigen and the functioning of various anatomical and cellular components which insure that the antigen will encounter the proper cells. Thus, the antigen-trapping step shown in Figure 3 is not simply an encounter between an "antigen gas" and a "cell gas" but, more likely, depends on special mechanisms that have evolved to insure efficiency of encounter.

Studies on the molecular structure and genetics of antibodies have yielded detailed information on the steps concerned with diversification and clonal commitment, and the remainder of this paper is devoted to these subjects.

The structure of γG immunoglobulin

The major emphasis is placed on the structure of γG immunoglobulin, for there are good reasons to believe that this most-prevalent class is representative of the main features of antibodies. We now know the covalent structure (amino-acid sequence and disulfide bonds) of an entire γG immunoglobulin molecule (Edelman et al., 1969). Although its three-dimensional structure and the details of the antigenbinding sites remain to be determined, we can say a good deal about the nature of diversity and specificity by comparing the entire structure with previously analyzed portions of other immunoglobulin molecules (for reviews of previous work, see Cairns, 1967; Killander, 1967; Edelman and Gall, 1969). This is meaningful because the threedimensional structures of the molecule and its combining sites depend on the amino-acid sequences of its polypeptide chains (Haber, 1964).

A schematic diagram showing the arrangement and features of the polypeptide chains in a typical human γG immunoglobulin molecule (Edelman et al., 1969) is given in Figure 4. The structure contains two identical light polypeptide chains (molecular weight 23,000) and two identical heavy chains (molecular weight 55,000). The disulfide bonds are linearly and periodically disposed in both chains, and it is striking that the light and heavy chains can be aligned so that their disulfide bonds are in register. Such an arrangement has implications for the evolution and function of the molecule, which I discuss below. Each light chain is linked to its neighboring heavy chain by noncovalent interactions and by a disulfide bond consisting of half-cystines V of each chain (Figure 4). Half-cystines VI and VII of the heavy chain form the two bonds that link these chains and the half-molecules together. Limited hydrolysis of the molecule with proteolytic enzymes, such as papain or trypsin, cleaves the molecule into Fab fragments, which contain the antigen-combining sites, and Fc fragments, which mediate certain effector functions (Porter, 1959).

Together, the light and heavy chains make up 660 amino-acid residues, and the symmetry of the molecule gives a total of 1320 residues in the entire structure. In considering the whole structure, one is struck by the linear regional differentiation of the molecule: the amino-terminal portions of light and heavy chains contain so-called variable regions, which appear to be concerned with antigen binding, and the remainder of the molecule consists of constant regions, which are devoted to effector functions. This sharp distinction must be qualified in the absence of detailed knowledge of the three-dimensional structure, but the chemical evidence strongly favors the demarcation. The definition of variable and constant regions relies on extensive analyses of the amino-acid sequence of different immunoglobulins that have been made in a number of laboratories. This subject has been critically reviewed (Cairns, 1967; Killander, 1967; Edelman and Gall, 1969), and no attempt is made here to analyze the subject critically or historically. For convenience, the protein Eu, the complete sequence of which has been determined, serves as a reference; obviously other proteins could be used as well.

Before I discuss the sequence data in detail, I should emphasize again that all the information for the specificity of antibodies is contained in the amino-acid sequences of their constituent polypeptide chains. It follows from the selection dogma that there must be many different sequences. Moreover, the bulk of the evidence suggests that the information is in both light and heavy chains (Singer and Doolittle, 1966). These facts pose operational problems, for antibodies even to a single antigen are heterogeneous, and it is not possible to determine an unequivocal amino-acid sequence on a complex mixture of proteins. Fortunately for research purposes, certain plasma-cell tumors (myelomas) of mouse and man produce large amounts of homogeneous immunoglobulins. Each myeloma protein appears to have a unique amino-acid sequence, although its general structure resembles that of heterogeneous immunoglobulin. Unfortunately, however, there is no general way of determining the activity or specificity of myeloma proteins for antigens. Therefore, we are faced with a peculiar dilemma in structure-activity determination: either we must study a

FIGURE 4 Structure of a human γG immunoglobulin molecule Eu from myeloma patient (Edelman et al., 1969). Site of cleavage by trypsin to form Fab(t) and Fc(t) fragments is indicated by dotted line. Half-cystines contributing to disulfide bonds are designated by Roman numerals. Ab-

breviations: V_H and V_L , variable regions of heavy and light chains; C_L , constant region of light chain; C_H1 , C_H2 , and C_H3 , homology regions in constant region of heavy chain; PCA, pyrollidonecarboxylic acid; CHO, carbohydrate.

myeloma globulin, the activity of which is unknown, or we must attempt to determine the amino-acid sequences of an indeterminately large mixture of specific antibodies. Some efforts are being made to circumvent this dilemma by searching for homogeneous antibodies (Haber, 1968) or for myeloma proteins with the capacity to bind antigens (Eisen et al., 1967). Regardless of the structure-activity problem, the evidence suggests that myeloma proteins are typical immunoglobulins and they are the main source of data on antibody diversity.

Amino-acid sequences of light and heavy polypeptide chains: variable and constant regions

The amino-acid sequence of the light, or κ , chains of protein Eu is shown in Figure 5. In multiple myeloma, light chains

FIGURE 5 Amino-acid sequence of the light chain of Eu. Positions in which amino acids differ in κ chains of the same subgroup (see Figure 6) are indicated by dots under the appropriate residues. Half-cystinyl residues contributing to disulfide bonds (see Figure 4) are placed in boxes; methionyl

residues are underlined. The V_L region extends to residue 108. Variant position at 191 is known to represent genetic polymorphism of the constant region, C_L . The allelic form has a leucine at this position. are excreted in the form of Bence-Jones proteins (Edelman and Gally, 1962), each with a unique primary structure. Because of their purity and relatively low molecular weight, the amino-acid sequences of a number of these urinary proteins have been determined (Hilschman and Craig, 1965; Titani et al., 1965; see also Cairns, 1967; and Killander, 1967). Comparison of the sequences of different Bence-Jones proteins reveals an unusual structure. The first 108 residues have 41 positions in which different amino acids may be replaced in different molecules, whereas the last 106 residues show a replacement only at position 191. Thus, the chain may be divided into a variable, or V, region and a constant, or C, region. The replacement in the C region at position 191 is a genetic polymorphism similar to that found in other proteins. The evidence indicates that a single autosomal gene specifies the C region; for example, individuals may be homozygous for valine or leucine at position 191 (Baglioni et al., 1966; Herzenberg et al., 1968).

The genetics of the V region are more complicated. No genetic markers have been identified, but examination of various proteins has indicated that V regions of κ chains fall into three subgroups which are nonallelic, i.e., each individual has at least three genes specifying the subgroups (Milstein et al., 1969). Indeed, on the basis of this finding and the evidence for only one C gene per haploid set, it appears that each chain is specified by one V gene and one C gene (Hood and Ein, 1968). The implications of this unusual situation are discussed in detail below.

Individual proteins within each V-region subgroup differ from one another, on the average, by about 10 residues. The sites of amino-acid variation and some examples of the types of substitution found in one subgroup are shown in Figure 6. In a sample of 15 proteins compared, there are 41 positions in the V_{κ} region in which replacements have been observed. On the average, there are somewhat more than two replacements per variable position, but certain positions (e.g., 96) have as many as five amino-acid substitutions. Other positions show no variation and, so far, no other amino acid has been found to replace a half-cystinyl residue. Most of the substitutions can be accounted for by single base changes in the codons corresponding to the amino acids replaced.

Although fewer examples of heavy chains have been studied, they also have V and C regions (Figure 7), as well as subgroups of V regions (Gottlieb et al., 1968; Hood, 1969, personal communication). The sequence of the Eu heavy chain (Edelman et al., 1969) has been compared with two other partial sequences, Daw (Press and Piggot, 1967) and He (Cunningham et al., 1969), and the data suggest that the variable region of the heavy chain (V_H) is about the same size as that of the light chain, so the constant region (C_H) is about three times as large. Trypsin cleaves the heavy chain at lysyl residue 222 to produce the Fc fragment. Isolation of a single glycopeptide indicates that the polysaccharide portion of the molecule (see Figure 2) is attached at asparaginyl residue 297. By comparison with the data of Thorpe and Deutsch (1966), it has been suggested (Edelman et al., 1969) that glutamyl residue 356 and methionyl residue 358 are associated with the Gm specificity and the genetic polymorphism of the Fc region. Similarly, the arginyl residue at position 214 probably is also associated with variation at the Gm locus. Thus, like the C_L region of the light chain, the heavy-chain C regions contain a few variants that are inherited in a classical Mendelian fashion. This fact poses a paradox: How can we account for the diversity of the V regions and the simultaneous constancy of the C regions?

Origins of diversity

The data on the amino-acid sequences provide a molecular basis for the diversity requirement in the selective immune response: the different amino-acid sequences of V regions result in different three-dimensional structures for the antigen-combining sites. How such a result is actually achieved will depend on the results of X-ray crystallography of antibodies. In the meanwhile, we are left with the equally challenging problem of the genetic origins of the diversity. Three theories (see Figure 8) have been proposed at the gene level: (1) There is a single V gene for each different V region and thus each organism contains an enormous number of V genes (Dreyer and Bennett, 1965). Although there is probably sufficient DNA for this purpose, the major problem posed by the theory is how such a large number of duplicated genes remained so alike. It is obvious that the individual antigens cannot have been responsible for the selection. Because of the great similarity of V genes (see Figure 6), very strong selective forces must be imposed to maintain gene constancy. In view of the fact that we can make many immunoglobulins which never serve as antibodies, the selection pressure must be small. Moreover, it is difficult to explain the evolution of V-gene subclasses and speciesspecific amino acids (Kabat, 1967) from a large number of similar genes. (2). There is one V gene for each type of chain, and it undergoes somatic hypermutation. After cell division, the mutants are selected for, by an as-yet-unknown principle, according to their capacity to make antibody molecules (Brenner and Milstein, 1966). This theory requires rapid and efficient somatic selection to favor those mutants that make properly folded antibodies (Cohn, 1968). The somatic mutation rate must be very high in order to produce sufficient variation in a small number of cell generations. This requires a special mechanism which affects V genes but not C genes or other genes that specify different proteins in the cells. Because of the nonrandom nature of the interchanges found in V regions, a highly efficient selec-

tive mechanism is required by their theory. So far, no convincing mechanism has been proposed. (3). There are a few V genes that have evolved to contain the mutations, and these genes recombine in the precursors of antibody-forming cells to provide the diverse variants required (Edelman and Gally, 1967, 1969). Such V genes would be similar but not identical. In certain positions, they are assumed to contain mutations that differ from gene to gene, and these mutations would have been selected for in the ensemble to

yield diverse sequences after somatic recombination. The genes, which have been preselected in evolution, would yield enormous diversity if they recombined frequently in the soma. Recombination of the tandem array of genes would occur intrachromosomally and would not occur between tandem arrays corresponding to V-region subgroups. This theory must explain how a small set of multiple V genes can have evolved as a unit; an attempt at such an explanation is given below.

FIGURE 7 Amino-acid sequence of the heavy chain of protein Eu. Positions in which amino acids differ in different heavy chains so far studied are indicated by dots. Because

these proteins are probably in different subgroups and therefore coded by different genes, the number of variable residues in a subgroup is expected to be fewer than indicated.

Although it has been proposed (Smithies, 1967) that only two genes are required for somatic recombination, such a suggestion seems to be ruled out by the existence of three amino acids in one position in light chains of inbred mice and by the existence of nonallelic (Milstein et al., 1969) Vregion subgroups. So far, none of the theories has been tested rigorously. Some confusion has arisen from the assumption that certain theories are easier to test than others. The obvious critical experiments are to count immunoglobulin genes by DNA-RNA hybridization techniques and to search for a genetic marker in V regions. Unfortunately, these experiments are

difficult to carry out. If a homozygous marker were found, however, the multigene germ-line theory (Dreyer and Bennett, 1965) and pauci-gene recombination theory (Edelman and Gally, 1967, 1969) would be weakened. The existance of a homozygous marker would suggest that there are at most a few V genes, because recombination and mutation of a large set of genes during evolution would tend to destroy homozygosity.

The translocation hypothesis, allelic exclusion, and the possible bases of clonal commitment

Besides providing a molecular basis for the diversification requirement in the selective immune response, studies of antibody structure have suggested ways in which the clonal nature of the system may have arisen (Edelman and Gally, 1969). As pointed out in the section on V and C regions, there are at least three V genes and only one C gene for κ chains in each haploid set. Because the heavy and light chains appear to be synthesized from a single starting point (Lennox et al., 1967; Fleischman, 1967), a mechanism must exist for transposing one of the V genes to the C gene so that a complete VC gene exists (Dreyer and Bennett, 1965; Gottlieb et al., 1968; Edelman and Gally, 1969). One mechanism by which such a transposition might occur is shown in Figure 9. By translocation and recombination, a

FIGURE 9 A hypothetical model for translocation of V genes to C genes. Episomal V gene crosses over with one of the two C genes, and the product is a single VC gene capable of being transcribed. Wavy lines indicate regions of recombination and integration.

FIGURE 8 Theories of diversity at the gene level. Germ line evolution: large set of V genes, one for each V region. Somatic point mutation: hypermutation of one or a few genes during development of organism followed by selection of products in the soma; x indicates different mutations in the V gene. Somatic recombination: a small set of V genes with mutations already selected for during evolution recombines in the lymphoid cell to give new combinations of sequences.

V-gene episome may be integrated into the genome, and a VC gene with the appropriate start signals may be formed. If this event were followed by transcription and translation, it would effectively represent an irreversible differentiation step. Of the vast set of sequences for which it has the genetic information, the cell could make only one or, at most, two of the heavy or light chains. In fact, as pointed out above, it has been observed that in a heterozygous individual with κ chains (see Figure 5) having valine and leucine at position 191, only valine *or* leucine is actually seen in immunoglobulin molecules from any given single lymphoid or plasma cell. This unusual phenomenon of *allelic exclusion* can be explained by the translocation hypothesis, for it is highly unlikely that both V genes from each parent would be simultaneously translocated.

Translocation is consistent with the observation that a committed cell has only one specificity (Mäkelä, 1967). The commitment to one type of antibody guarantees that there will be no loss of specificity in the system, and thus diversification is coupled to amplification (see Figure 3) in an unequivocal fashion. This, in turn, would assure that the cell is most efficient in amplifying the synthesis of its antibody molecules. It should be pointed out that the translocation hypothesis has not been proved nor has the mechanism of translocation been studied; nevertheless the hypothesis appears to be compatible with the evidence on antibody structure.

Evolution of antibodies: gene duplication and the domain hypothesis

An examination of the structure of γG immunoglobulin provides evidence to support a scheme for the evolution of the antibody molecule to serve both antigen-binding functions and effector functions. Protein sequences may be compared for identical or similar residues by visual inspection. In addition, a scheme has been developed (Fitch, 1966a, 1966b) for comparing polynucleotide sequences that correspond to the protein sequences. If due caution is used

FIGURE 10 Homology in V regions of protein Eu. Identical residues in the amino-acid sequences of V_L and V_H are shaded. Deletions indicated by dashes have been introduced to maximize the homology.

(Nolan and Margoliash, 1968), one may find evidence for evolutionary homology, which in general suggests evolution from a common gene precursor. Comparisons (Figures 10 and 11) of the V_L, V_H, C_L, and C_H regions of protein Eu show that there are a number of homologies in the sequences. These are schematized in Figure 12. V_L and V_H regions are homologous to each other and C_L is homologous to three adjoining regions of C_H known as C_H1, C_H2, and C_H3. V regions do not show any obvious homology to C regions.

In accord with these findings, we may modify the original suggestion of Hill et al. (1966) on the evolution of immunoglobulins in the fashion shown in Figure 13. In this hypothesis, immunoglobulins arose by divergence of V and C genes, each capable of specifying a polypeptide chain of about 110 residues. Gene duplication and subsequent variation then accounted for the development of the various kinds of V regions and C regions. Evolution of a translocation mechanism to join V and C genes would result in a complete gene specifying a molecule with linear differentiation of function: V regions for ABF and C regions for EF (Figure 13).

Such a proposal is in accord with the covalent chemistry and symmetry of the molecule. There is a rotational symmetry axis in the Fc region which passes through the interheavy-chain disulfide bonds and contains the homology regions C_H2 and C_H3; in addition, a pseudosymmetry axis may exist between V_H and V_L and C_L and C_H1 (see Figure 4). On these and other grounds, it has been proposed (Edelman and Gall, 1969; Edelman et al., 1969) that the immunoglobulin molecule is folded in compact domains, each consisting of a homology region containing at least one active site and serving a separate molecular function (Figure 14). Each domain is stabilized by one disulfide bond and is linked to neighboring domains by less compactly folded stretches of the polypeptide chain. Within each group of V or C homology regions, the domains would have similar but not identical tertiary structures. V_H and V_L serve antigen-binding functions and are the only domains for which the function is known. C_L and $C_H 1$ may

FIGURE 11 Homology in C regions of protein Eu. Identical residues are darkly shaded. Dark and light shadings are used to indicate identities that occur in pairs in the same positions.

I. EVOLUTION OF V AND C GENES

FIGURE 12 Diagram summarizing internal homologies in the structure of γG immunoglobulin. Variable regions V_H and V_L are homologous. The constant region of the heavy chain (C_H) is divided into three regions, C_H1, C_H2, and C_H3, which are homologous to one another and to the C region of the light chain (C_L).

FIGURE 13 Hypothetical scheme for evolution of antigen-binding functions (ABF) and effector functions (EF) of immunoglobulins.

FIGURE 14 The domain hypothesis. Homology regions (see Figure 11) that constitute each domain are indicated. V_L , V_H : domains made up of variable homology regions; C_L , C_H1 , C_H2 , C_H3 : domains made up of constant homology regions. Within each of these groups, domains are assumed to have similar three-dimensional structures, and each is assumed to contribute to an active site. The V domain sites contribute to antigen recognition functions and the C domain sites to effector functions.

serve to stabilize the interaction of the V domains but may also play a role in triggering the cell to mature after encounter with the antigen. $C_{\rm H2}$ domains contain the carbohydrate that appears to be required for export of the molecule from the cell (Melchers and Knopf, 1967; Moroz and Uhr, 1967). $C_{\rm H3}$ domains may contain sites for skin fixation, but so far no function has been determined for these regions.

Verification of the domain hypothesis will depend on electron microscopic and X-ray crystallographic analysis of the three-dimensional structure of antibodies. This hypothesis and the evolutionary scheme discussed above suggest an over-all sequence of events in the evolution of the selective immune response. The first evolutionary event may have been the development of a diversification mechanism to yield a sufficiently wide variety of antibodies. These antibodies may have been fixed to cells similar to those concerned with delayed hypersensitivity reactions. Subsequent development of C genes, translocation mechanisms, and carbohydrate fixation allowed for export of antibodies and for diversification of effector functions, each mediated by a specific domain. This would account for the evolution of classes of antibodies other than the γG immunoglobulins. These classes have similar light chains, but each has a distinctive kind of heavy chain and different effector functions. At present, however, too little is known of the amino-acid sequences of the immunoglobulins of lower forms to specify the detailed order of emergence of classes. Nevertheless, there is some suggestion that γM immunoglobulins (see Figure 1) were among the

first antibodies to evolve (Marchalonis and Edelman, 1965, 1966, 1968).

The sequence of events described above suggests that, once a mechanism of diversification was present, the major evolutionary developments to improve the selective immune response were focused on the amplification mechanism (see Figure 3) and on the refinement of effector functions (Marchalonis and Edelman, 1968).

The foregoing remarks have been concerned with the antibody system itself. In the three last sections of this paper, some possible implications of the data for more general problems of protein structure and evolution and differentiation are discussed briefly.

Implications for protein structure in general

Gene duplication has been implicated in the evolution of proteins other than immunoglobulins, such as ferredoxin (Eck and Dayhoff, 1966) and haptoglobin (Black and Dixon, 1968). In addition, evidence has been obtained for multiple structural genes for polypeptide chains of hemoglobin (Schroeder et al., 1968; Hilse and Popp, 1968). These proteins do not have the peculiar periodic structure seen in immunoglobulin, however. Certain other proteins made up of polypeptide chains of great length, such as β -galactosidase, may have arisen by gene duplication and are arranged in domains. Tandem homology regions in multichain structures can be arranged in a variety of ways across symmetry and pseudosymmetry axes, and such arrangements may be evolutionarily advantageous-particularly if there is a need for linear differentiation of function. It would not be surprising, therefore, if tandem homology regions were found more generally in large proteins. It is already clear that the classical division of proteins into "globular" and "fibrous" may require additional categories, for γG immunoglobulin is not a classical globular protein (Valentine and Green, 1967).

The structural findings on Bence-Jones proteins and immunoglobulins may also have a direct bearing on the profound problem of determining tertiary structure by primary structure (Perutz et al., 1965). Bence-Jones proteins may be uniquely suited for the experimental analysis of this problem. They represent the only large family of related proteins of low molecular weight that have been selected to have *variable* three-dimensional structures. They represent a diverse set of amino-acid sequences disposed around several basic patterns, such as the subgroups of κ and λ chains. Thus, their V regions have presumably evolved for variation in shape, and the C regions for conservation of shape. Although not conclusive, there is evidence (Edelman and Gally, 1962) that each Bence-Jones protein has a different tertiary structure. Moreover, Bence-Jones proteins can be crystallized and, because of their low molecular weight, it should not take an excessive time to analyze them by X-ray crystallography, provided that suitable isomorphous derivatives are obtained.

From a comparison of a number of Bence-Jones protein sequences and three-dimensional structures, rules may emerge which will shed light on the folding problem. Moreover, if the domain hypothesis is correct, the threedimensional structure of Bence-Jones proteins should resemble that of corresponding portions of antibody molecules.

Antibodies and the problem of multiple genes: a hypothetical mechanism for democratic gene conversion

Multigene theories and the pauci-gene somatic recombination theory for the origin of antibody diversity require the existence of a number of very similar V genes in a tandem array. Such an array could have evolved by nonhomologous crossing over between misaligned genes. Such a process also may have led to the development of homology regions $C_{\rm H}1$, $C_{\rm H}2$, and $C_{\rm H}3$ of C gene subclasses (Kunkel et al., 1964) and the evolution of classes of heavy chains. Obviously, the rate of duplication must have been higher than in other proteins. Once two genes are tandemly arranged by this means, however, the number of genes could increase rapidly by crossing over among genes paired in phase but out of register.

The existence of multiple genes poses the problem of explaining how the set appears to evolve as a single unit. This problem is not unique to the antibody system, as is pointed out elsewhere in this book (Edelman and Gally; Thomas). For example, structural genes for ribosomal RNA (Ritossa and Spiegelman, 1965; Wallace and Birnstiel, 1966) and for 5 S and transfer RNA (Ritossa et al., 1966) appear to be repeated many times in higher organisms, yet they give relatively homogeneous products (Forget and Weissman, 1967; Pinder et al., 1969).

A mechanism based on the recombination process itself has been proposed (Edelman and Gally, 1969, and this volume) to account for the evolution of multiple genes as units. It is assumed that, in this mechanism, recombining genes in a tandem, duplicated set are compared with one another by heteroduplex DNA formation (Figure 15). As shown in Figure 15, recombination is assumed to occur by breakage, reunion, and repair, and DNA synthesis during repair leads to gene conversion (Holliday, 1964; Fogel and Mortimer, 1969; Stahl, 1969) or nonreciprocal recombination. In this way, genetic information can be transferred among genes within a set as in the "master-slave" system proposed by Whitehouse (1967). The process described here is more democratic, for, although there is a strong tendency for conformity, no one sequence is imposed on the V genes. In any of the V genes, a point mutation that is selectively advantageous could spread rapidly along the set rather than having to occur independently. Chromosomal rearrangements could separate sets of V genes so that each set could become differentiated, while genes within a set remained relatively similar to one another.

This gene-conversion mechanism could explain how relatively few tandem duplicated genes might remain similar. On the other hand, it is difficult to imagine how this process could account for rapid changes in a very large set of genes. This problem remains as one of the major obstacles to understanding the evolution of duplicated genes in eukaryotic genomes.

FIGURE 15 Scheme of democratic gene conversion. Solid horizontal lines represent strands of DNA that comprise two sister chromatids containing a set of immunoglobulin V genes. The V genes are aligned in register, but there is pairing between nonidentical genes. Solid and open circles represent point variation in one of the genes of the set; other genes contain other variations, which are omitted for the sake of simplicity. A. Single-strand nicks and excisions are made in complementary strands of opposite chromatids. B. Double helix is formed between two partially excised strands, allowing DNA repair synthesis to occur, as shown by dotted lines. C. Newly synthesized regions are incorporated into original two chromatids, resulting in formation of heteroduplex DNA. The net result is elimination of point variation from one strand of one chromatid and duplication of other point mutations of the set. By frequent repetition, point mutations could become represented multiply along both strands or be eliminated from the set, depending on selective pressures. Similar processes could occur intrachromosomally or between tandem genes of paired homologous chromosomes. The only essential feature of this model is repair synthesis in strands of hybrid DNA.

The relevance to differentiation in eukaryotic organisms

In one sense, commitment of an antibody-forming cell can be considered a well-marked and irreversible differentiation event. Compared with other organic differentiation events at the cellular level, differentiation of antibody-forming cells appears to be distinguished by a kind of microscopic singularity. In other differentiated organ systems, such as the liver, one can certainly find more than two cells that are alike. In the kind of differentiation event seen in antibody production, however, each lymphoid cell appears to differentiate to produce one particular kind of antibody molecule. At the stage of commitment, therefore, one is likely to find a high degree of cellular singularity, with each cell producing a different antibody. Of course, after stimulation of committed cells by antigens, there are whole clones of similar or identical cells. In view of the changing patterns of antigenic exposure, no two individuals, even uniovular twins, would be expected to have similar populations of lymphoid cells. The analysis of the population dynamics of these cells is one of the challenging areas of modern immunology.

At present, it is not clear whether the mechanisms of cellular maturation and clonal commitment of antibodyforming cells will have a general bearing on differentiation processes in eukaryotic organisms. The indication that eukaryotic genomes contain multiple copies of genes (Britten and Kohne, 1967) and the long-standing example of transposition of genes in maize (McClintock, 1965) have certain resemblances to some of the unusual features of the antibody system. If these processes are related to differentiation in eukaryotes, it is clear that a study of somatic genetics and of events at the DNA level of somatic cells should be particularly rewarding. Inasmuch as the study of somatic genetics is still difficult, analyses (Lindahl and Edelman, 1968; Lindahl et al., 1969) of enzymatic mechanisms of repair and recombination in eukaryotic cells may also provide valuable information both on the immune response and on other specialized manifestations of cellular differentiation.

Summary

Antibodies constitute a molecular recognition system that carries out two major functions in the immune response: (1) binding to a great variety of sterically different antigen molecules (antigen-binding function or ABF); and (2) mediating essential immune reactions within the organism, such as complement fixation (effector functions or EF). The ABF is *selective*, i.e., the information for synthesizing antibodies to a large range of chemically different antigens *already* exists in the organism before exposure to these antigens. Particular antigens serve only to stimulate (and thereby select) those antibody-forming cells that synthesize antibodies having appropriately complementary antigenbinding sites. This process requires that the number of sites must greatly exceed the number of different antigens. Furthermore, there must be an exceedingly efficient system for amplifying the production of specific antibodies after stimulation by injection of a particular antigen. This appears to be achieved by maturation and cell division of stimulated cells, each of which synthesizes only one kind of antibody. Division and maturation are followed by an increased synthesis of that particular antibody by the clonal progeny of the stimulated cell.

Studies of the molecular structure of antibodies or immunoglobulins have been useful in an analysis of some of the mechanisms of the selective immune response. The covalent structure of an entire γ G immunoglobulin (molecular weight 150,000) has been determined and compared with portions of other immunoglobulin molecules analyzed by other workers. The light and heavy polypeptide chains of the molecule each consists of a variable, or V, region for antigen binding and a constant, or C, region for effector functions. The amino-acid sequences of V regions differ from molecule to molecule, whereas the sequence of C regions is relatively invariant. The mechanism by which diversification of amino-acid sequence is achieved in antibody V regions has not been established, but several theories on the origin of diversity have been proposed and are reviewed.

The amino-acid sequence of γG immunoglobulin shows a linear periodic arrangement which suggests the evolutionary origin of the molecule by gene duplication. It is proposed that the molecule is arranged in successive compact domains organized about axes of symmetry and pseudosymmetry. According to this proposal, *domains* of V regions mediate antigen binding, and successive domains of the C regions mediate different effector functions. This is in accord with the hypothesis that the antibody molecule evolved from two genes, V and C, each of which underwent successive duplication.

The analysis of antibody structure suggests the possibility that a number of unusual genetic mechanisms may be required to account for the evolution of selective recognition systems. Evidence from several laboratories has led to the conclusion that each polypeptide chain is specified by a V gene and a C gene. It is suggested that the V gene may be translocated in the lymphoid cell to form a single VC gene. Translocation could account for the clonal nature of the selective response, for, although each cell may have information for many V sequences, genetic analysis indicates that it has at most only two C genes for each chain. Translocation would commit the cell to the expression of the smallest possible number of antibody chains and help to maintain the specificity and efficiency of the selective immune response.

The Origin of Specificity in Binding: A Detailed Example in a Protein-Nucleic Acid Interaction

F. M. RICHARDS, H. W. WYCKOFF and N. ALLEWELL

ENZYMES INTERACT with a vast array of small molecules and macromolecules and cause changes in the covalent structure of these substances. Individual enzymes differ widely in both substrate specificity and turnover number. For the over-all catalytic process, the simple enzymes manage to carry out the series of binding and bond-altering steps with structures composed solely of the amino acids as building blocks. There is no compelling evidence for the existence of any fundamental forces or types of interaction that are not found in small molecules (Kauzmann, 1959; Jencks, 1966; Koshland and Neet, 1968). The mystery appears to lie in the three-dimensional assembly of the basic units into a cooperative system, the dynamic behavior of which provides simultaneously the required degree of specificity toward potential interactants and the enhanced reactivity, required for catalysis, of functional groups in the enzyme, the substrate, or both. Our understanding of these systems does not yet permit prediction of the structure required for a given reaction. We are beginning, however, to be able to look in detail at the actual structures of a few enzymes and of some of their complexes with small ligands, and we hope that a limited set of structural ground rules will eventually emerge.

General and detailed three-dimensional structural information on proteins is available only from diffraction studies on single crystals (Dickerson, 1964; Phillips, 1966). The best that can be done presently is the specification, within certain limits of confidence, of the average position of the atoms in the structure. Considerable prior chemical information is normally assumed in the interpretation of the data, i.e., covalent-bond distances and angles and amino-acid sequences. Although the diffraction patterns are affected by vibrations of atoms and librations of groups of atoms, such information cannot be extracted with confidence from data of the extent and accuracy now available. For such problems in molecular dynamics, the various spectroscopic techniques are much more promising, especially with the X-ray structures as starting points.

Noncovalent forces affecting conformation

The tendency of water to try to squeeze hydrocarbons out of solution is responsible for a large fraction of the energy involved in stabilizing the compact shape of most globular proteins (Kauzmann, 1959; Davidson, 1967). On a more detailed level, this tendency may be thought of as the energy derived from decreasing the surface area of the solvent cavity surrounding the solute molecule; the more compact and spherical the molecule, the smaller the surface area and the lower the energy (Sinanoğlu, 1968). Although the emphasis is different, the solvent entropy effects (Kauzmann, 1959; Némethy and Scheraga, 1962; Scheraga, 1963) are contained in this more recent theory. Unless markedly different polarizabilities are involved, dispersion forces probably do not make a major contribution, because roughly the same number of contacts will be made between atoms in the folded protein and between solvent and atoms in the unfolded chain. For the same reason, the interactions between polar groups (for example, hydrogen bonds) also may not contribute to the stabilization energy, but they can have a dramatic influence on the final structure because of their directional nature and the requirements for orientation and group pairing when solvent interactions are removed. In this sense, such interactions make incorrect structures highly improbable instead of providing deep-energy minima for the correct structure. Coulombic forces between formal charges are of uncertain general importance but are clearly significant in certain special cases. Quantitative calculations present formidable problems, especially as net stabilization energy in each of these cases is invariably the small difference between large numbers. Superimposed on these attractive "forces" are the geometrical requirements for packing (van der Waals' repulsion) and the steric limitations imposed by the covalent-bond distances and angles implied by the amino-acid sequence. The combination of these many effects that are attributable to individual atoms or groups of atoms leads to the structure of the "resting" enzyme at the point of the lowest accessible free-energy minimum. The same considerations apply to the interaction of ligands with the "resting" enzyme. The specificity must be controlled by certain directional forces and the geometrical packing requirements.

F. M. RICHARDS, H. W. WYCKOFF, and N. ALLEWELL Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, Connecticut

Specificity

The term specificity is used in many ways, even within the restricted field of protein chemistry. Enzyme-catalyzed rates of reaction may differ markedly among a series of related substrates. For a given enzyme, a fast relative rate for a particular substrate among a group of substrates is usually cited as evidence of a high degree of specificity. The term may refer, however, to the maximum turnover number or to a velocity at some fixed substrate concentration, a number that may contain both the turnover rate and binding parameters. With antigen-antibody reactions, specificity is more clearly tied to differences in the binding constant for a given antibody preparation and a series of related antigens. In this case, high specificity is usually thought to be synonymous with large association constants. The word specificity is ambiguous unless qualified.

STATIC SPECIFICITY This term applies to associating systems at thermodynamic equilibrium.

1. From one point of view the *free energy of association*, as reflected in the *binding constant*, may be used to describe static specificity. The degree of specificity is then related to the *differences in free energy* for the associations of a given molecule with a series of different ligands. The absolute value of the free energy is *not* related to specificity. Very tight binding of a number of ligands does not constitute specificity. The latter term refers only to differences in binding energy. For analytical tests or chromatographic separations, for example, such considerations alone may be adequate. For other problems, however, the free energy of binding may be of secondary importance and, in fact, may not be a useful aspect of specificity at all.

2. From this second point of view, the geometry of the complex is the important point. Here the energy is relevant only in that the binding constant must be such that the partners are brought together. The specificity is now considered in relation to the detailed structures of the various associated pairs in a series of complexes. Discrimination can occur, even if all the binding constants are identical. The differences in geometry may show up in any of a number of physical or chemical properties of the complex, i.e., spectral perturbations, titration behavior, and so forth.

KINETIC SPECIFICITY This adds to static specificity the consideration of the activation parameters of reacting systems.

1. In *transient-state* kinetics, specificity implies the existence of multiple paths for a given reaction, with the principal path governed by the properties of the reactants. There is an intimate correlation between geometry and reaction mechanism. Thus, the differences in the activation-free energies and the transition-state geometries are probably in-

extricably intermingled (Jencks, 1966). A pertinent example is the folding of an extended peptide chain to produce an apparently unique functional protein. The kinetic path determines the useful structure and a local energy minimum. On an infinite time scale, this structure may or may not represent the lowest energy conformer demanded by thermodynamics.

2. In steady-state kinetics, the possibility of rate-limiting steps and pools of intermediates in quasi-equilibrium requires a mixture of all the above considerations. In studies of enzyme catalysis, the geometrical factors become particularly clear when a slight shift in ligand structure changes a substrate to an inhibitor or when apparently related inhibitors with similar inhibition constants can be shown to be bound at spatially separate sites.

In the present paper, we focus on packing geometry and on the hydrogen bond as a specific type of dipole interaction. The complexes of lysozyme and ribonuclease with certain inhibitors are used as examples.

Hydrogen-bonding groups in proteins

The principal hydrogen bonds in proteins involve only oxygen and nitrogen atoms as donors, D, acceptors, A, or both. A hydrogen bond, D-H---A, is assumed to exist when the hydrogen-acceptor atom distance is significantly (>0.2 Å) less than the sum of the van der Waals' radii. For N-H---O bonds, the N-O distance is usually less than 3.0 Å. The D-H---A bond angle is frequently not 180 degrees and may differ from that value by as much as 30 degrees. The acceptor atom is attached to another group, R, and the angle D---A-R is found to be highly variable and not significantly correlated with the electron orbital structures proposed for the acceptor atoms. The hydrogen bond is clearly electrostatic in origin, but its directional character can be specified only within rather broad ranges. Donor and acceptor atoms are easily recognized, and the required pairing of such groups produces rather severe restrictions on protein structures, even though the individual bond geometry is quite flexible. Bifurcated hydrogen bonds, in cases in which a single hydrogen atom is shared between two acceptor groups, are rare, but they do exist, and must be kept in mind when one is considering possible structures. Donohue discussed these points in a recent review (1968).

The amino-acid residues that can form hydrogen bonds are indicated in Figure 1. A survey of this list shows a variety of possible types of behavior, but also some clear restrictions. The nitrogen of the *tryptophan* ring, A, can serve only as a hydrogen donor. The partner must be an acceptor atom, its position is closely defined with respect to the ring system, and this, in turn, is always found firmly fixed in the protein structure. *Arginine*, B, is also an obligate hydrogen donor, but with many possible acceptor sites. A

particularly good cooperative bond might be made between the guanidinium group and an ionized carboxyl group. A pair of hydrogen bonds would be formed with the coulomb energy of the ion pairs as a bonus. Other factors, however, seem to be more important in crystals of arginine salts (Mazumdar et al., 1966), and, although such bonds may be found in papain (Drenth et al., 1968), other proteins-for example, ribonuclease (Kartha et al., 1967; Wyckoff et al., 1967) and lysozyme (Blake et al., 1965)appear to have none. The main chain, C, can serve as both donor and acceptor, but the chain geometry will normally be fixed, so the external acceptor and donor atoms will have fixed positions and cannot be interchanged. The terminal amide groups of asparagine and glutamine, D, usually on the surface, may or may not be firmly fixed by the rest of the protein structure. Rotation about the terminal C-C bond may be sterically possible, and either a donor or acceptor group at a given position could be accommodated. The aliphatic hydroxyl group of serine and threonine, E, can easily be either a donor or acceptor, with only the movement of a single proton. (The change is shown symbolically as rotation, although it could equally involve exchange with water molecules—a process that takes place rapidly with OH groups in aqueous solution [Hvidt and Nielsen, 1966].) The ionizable functional groups, F through I, show the same range of characteristics, but have, in addition, the variations implied by the conjugate acid and base forms. Oxygen and nitrogen atoms behave in a reciprocal manner. Protonation of an oxygen atom converts an obligate acceptor to a donor-acceptor group (D/A group). Protonation of a nitrogen atom converts an acceptor or D/A group to an obligate donor.

The particular properties of imidazole, I, should be noted. If, in the free base form, the single proton in either position 1 or 3 of the ring is bonded to an obligate acceptor atom in some other fixed part of the protein structure, the remaining nitrogen atom can be protonated with no resulting structural change. If the free nitrogen is bonded to an obligate donor, however, the imidazole group is forced to stay in the conjugate base form, unless a substantial change in ring position is permitted in order to allow space for the added proton in the conjugate acid. As a minimum con-

FIGURE 1 Hydrogen bonding groups available in simple proteins. The symbol A stands for an acceptor atom, the symbol D for a donor atom. The hydrogen atom provided by the donor is not shown. The diagram is approximately

to scale, to indicate the geometry implied by these interactions. The variation in hydrogen-bond geometry is discussed in the text.

formational change, rotation around $C\alpha$ - $C\beta$ or $C\beta$ - $C\gamma$ of the histidine residue would be required.

Lysozyme-inhibitor complexes

The elegant work of Phillips and his colleagues on the structure of lysozyme (Blake et al., 1965) and some lysozyme-saccharide complexes (Blake et al., 1967) provides specific examples of some of these points. The hen eggwhite enzyme catalyzes the hydrolysis of polymers of Nacetylglucosamine (NAG) and appropriate copolymers containing this group, and N-acetylmuramic acid (NAM) as found in certain bacterial cell walls. The structure of a nonproductive complex of the enzyme and the trisaccharide tri-NAG has been determined by X-ray diffraction techniques. A schematic diagram showing a single NAG residue and some of the surrounding parts of the enzyme is given in Figure 2. This C site makes the largest contribution to the association constant of the trisaccharide (Chipman et al., 1967). The hexose is in the "chair" conformation with the 6-hydroxyl group bonded to tryptophan 62 and the 3-

FIGURE 2 Schematic diagram of part of the hexose binding site C in egg-white lysozyme. Parts of the main peptide chain are shown as heavy lines, with the residue numbers indicated. Two tryptophan residues of the enzyme and an N-acetylglucosamine residue of the inhibitor in the chair conformation are shown. The dashed lines are hydrogen bonds. This figure is adapted from Blake et al. (1967).

hydroxyl group to tryptophan 63. The most interesting interaction is shown by the acetamido group of this NAG residue. The carbonyl function is bonded to the chain NH of residue 59, and the NH function is bonded to the chain carbonyl of residue 107. The obligate donor and acceptor character of the two main chain groups is fixed. The peptide unit is the only one that could be attached to the sugar and that would have the necessary geometry, dimensions, and H-bonding character. The methyl group of the acetyl function fits into a pocket in the protein. Bulky groups would be sterically excluded.

Such an example is one of strict geometrical specificity. The effect is provided by a combination of the three clearly identifiable interactions-two hydrogen bonds and the packing requirements of the methyl group. The single amide carbonyl bond to NH 57 localizes the oxygen atom fairly well, but by itself would put little restriction on the more remote atoms of the NAG group. The addition of the NH bond to CO 107 markedly restricts the possibilities, but there might still be free rotation about an axis connecting the two oxygen atoms without violating the geometry of the H bonds. The final addition of the methyl-group packing locks the group in three dimensions and closely defines the N-C2 bond direction. The combination of the three unit interactions of low specificity can thus produce a group interaction of high specificity. In general, many interactions will be involved in the ligand-enzyme complex as a whole. If a particular group is absent or is situated in a different position, the ligand might still interact with the enzyme in much the same way, but its binding constant, its orientation, or both might be affected. The difference in the binding of the stereoisomers α -NAG and β -NAG is a good example of this effect (Blake et al., 1967). The acetamido side chain is in the same location in each case, but the sugar ring is oriented quite differently.

From this binding study, Phillips deduced the binding of a hexasaccharide substrate and proposed a mechanism for the catalytic splitting of the chain, which has been validated by all subsequent chemical work on lysozyme up to the present. The substrate binding produces a strained conformation, the half-chair, in the appropriate sugar ring-the D residue in the hexasaccharide. The glycosidic oxygen is protonated by a neighboring carboxyl group. The transient carbonium ion is stabilized by a carboxylate function on the opposite side of the susceptible bond. After one product is replaced by a water molecule, the steps are reversed to complete the reaction. During all these binding and catalytic steps, no part of the resting enzyme has been observed to move, or need be assumed to move, more than an Angstrom unit. The catalysis is assumed to be intimately related to the strained conformation of the substrate induced by its association with the enzyme. This example is an excellent one of the principle, suggested by Pauling (1946, 1948), that an enzyme

should be designed to interact with the transition-state structure and not with either substrate or product.

Structure of ribonuclease

Bovine pancreatic ribonuclease is a hydrolytic enzyme with a single chain of 124 amino-acid residues. The sequence has been reported by Smyth et al. (1963). The three-dimensional structure of the native enzyme, ribonuclease-A, has been worked out by Kartha et al. (1967); that of the modified but catalytically active form, ribonuclease-S, by Wyckoff et al. (1967). The ribonuclease-S system is shown schematically in Figure 3. Cleavage of a peptide bond near residue 20 per-

FIGURE 3 Schematic diagram of the ribonuclease-S system. The irreversible cleavage of a single peptide bond is shown at the top, followed by the reversible dissociation of the product into S-protein and S-peptide. Appropriate denatured forms of ribonuclease-A will interact with S-protein to regenerate activity as a hybrid dimer (an example of in vitro complementation). (This Figure taken from Richards, 1964)

mits separation of the enzyme into two parts, S-peptide (residues 1-20) and S-protein (residues 21-124). The two parts can be dissociated and recombined with concomitant loss and restoration of enzymic activity.

A number of derivatives of S-peptide have been synthesized by K. Hofmann and E. Scoffone and their respective colleagues (Hofmann et al., 1966; Scoffone et al., 1968). The ability of these derivatives to bind to S-protein and to regenerate catalytic activity has been tested. The substitution of histidine 12 with the closely related analogues β (1-pyrazolyl)alanine or β (3-pyrazolyl)alanine completely eliminates enzymic activity (Hofmann and Bohn, 1966). The significance of histidine 12 for the activity of the enzyme is discussed below. The replacement of phenylalanine 8 by a tyrosine residue has little effect on the peptide-protein binding or on the activity of the complex (Marchiori et al., 1966). This observation is interesting in connection with general protein structure problems.

A stereoscopic view of the positions of the α -carbon atoms of the peptide chain of ribonuclease-S is shown in Figure 4A. The numbered planes refer to sections in the electron-density map from which this model was derived (Wyckoff et al., 1970). The contents of part of sections 17 through 24 can be seen in Figure 4B, in which the viewing direction is normal to the planes of Figure 4A. The rings of all three phenylalanyl residues can be seen in this diagram: 46, 120, and 8 (8 is just below 120 but unnumbered). Histidine 12, threonine 45, and valine 43, which are important in the active site of this enzyme, are also seen. One can get some impression of the complexity of the packing geometry from this diagram. The simplicity of regular structures, such as the α -helix or β -pleated sheets, which do occur in this protein, is lost in a welter of detailed interactions between side chains. Phenylalanine 46, for example, is seen to be completely surrounded. Residues at the top and bottom of the ring cavity (not shown) complete the enclosure and prevent any access from external solvent.

Phenylalanine 8 is in a similar cavity, but one that is less tightly packed than that surrounding phenylalanine 46. The implication of the finding of Marchiori et al. (1966) on the substitution of tyrosine for phenylalanine at position 8 is that the structure of this modified enzyme must be very similar to that of ribonuclease-S and that tyrosine 8 must fit into the same spot as phenylalanine 8 normally does. There is probably space to accommodate the extra OH group, but there are no accessible groups to satisfy the presumed Hbonding requirements of this phenolic OH. Possibilities of this kind increase the difficulty of developing reliable packing rules.

Wyckoff (1968) has considered the possible structure of pancreatic ribonuclease from the rat in the light of the known sequence (Beintema and Gruber, 1967) and the three-dimensional structure of the bovine enzyme. There are 41 differences in the sequences of the rat and bovine enzymes. If one assumes that the two enzymes have the same backbone conformation, one can examine each residue in turn to see if the changes are sterically permissible or reasonable. All the changes can be accommodated in the bovine structure. Beyond that there appears to be a significant pairing of the charges. Residues that are spatially close frequently change by the simultaneous loss (or gain) of both

FIGURE 4 Stereodiagrams of ribonuclease-S. A. Outline of peptide chain. Residue numbers are shown at the positions of the carbon- α atoms. The horizontal planes are sections through the molecule corresponding to sections in the electron density map (reprinted from Figure 4A in Wyckoff et al., 1969). B. Part of the volume between sections 17 and 24. All nonhydrogen atoms are shown. The main chain bonds are black. N and O atoms are labeled. X refers to N

or O or N or C where the assignment is uncertain. Residue numbers are given on α and β carbon atoms. The view is perpendicular to the sections shown in A and down from the top. Stereoviewers may be obtained from various suppliers, for example: Abrams Instrument Company, Lansing, Michigan, model CF8; Wards Natural Science Establishment, Inc., Rochester, New York, model 25 W 2951.

a negative and a positive group. Thus, not only the net charge but the charge distribution remain remarkably constant. In the interior of the molecule, addition of a methylene group to one residue is accompanied by the removal of such a group from a neighboring residue. If, in fact, the three-dimensional structures of the two enzymes are so similar, these observations lead to the concept of *paired iso-steric replacements*. Whether this will be the exception or the rule remains to be seen. (See, for example, the comparison of lysozyme and α -lactalbumin discussed by Browne et al., 1969.)

Interaction of ribonuclease with nucleotides

Pancreatic ribonuclease hydrolyzes single-strand RNA chains in a two-step process: (1) cleavage of the chain with the formation of a pyrimidine 2', 3' cyclic phosphodiester on one side of the bond cleaved and a free 5' OH group on the other side; and (2) hydrolysis of the cyclic diester end group to give the free 3' monophosphate ester. The enzyme is specific for pyrimidine bases on the 3' side of the bond that is cleaved, and the 2' OH of the ribose is an absolute requirement for activity. The crystallographic study of complexes of the enzyme with various nucleotides is now well under way (Allewell, 1969). At the moment, this system provides the only available detailed information close to the atomic level on the interaction of a protein and a nucleic-acid moiety.

The free 3' pyrimidine nucleotides are strong competitive inhibitors of ribonuclease. Both uridine-3'-phosphate and cytidine-3'-phosphate appear to bind in almost precisely the same place on the enzyme. A schematic diagram is shown in Figure 5; a stereoscopic view, in Figure 6. Both uracil and

FIGURE 5 Schematic diagram of the interaction of A, 3'uridylic acid and B, 3'-cytidylic acid with ribonuclease-S. Selected parts of the protein are shown. The hydrogen bonding flexibility provided by the aliphatic OH donor/ acceptor groups is shown, together with the fixed requirements of the chain NH group (an example of partial specificity). The nature of the histidine 12 involvement is discussed in the text.

cytosine have a carbonyl group in position 2. The chain NH group, an obligate donor, is seen to form a bond to the oxygen atom on C2. Positions 3 and 4 are either donors or acceptors, depending on whether the base is uracil or cytosine. The protein partners are of the D/A variety, both being aliphatic OH groups. The binding site thus provides an example of partial geometrical specificity. The N-H---O bond to position 2 is nearly straight, but is not in the plane of the pyrimidine ring. In position 3, the bond to both uracyl and cytosine is not quite straight, although it is probably within acceptable limits. The angle can be improved by slight rotation of the side chain of threonine 45 around the carbon α -carbon β bond. The bond to the NH₂ group in position 4 of cytosine is markedly nonlinear and probably is not acceptable for a bond of any strength. Substantial motion of serine 123 would be required to straighten this bond. This residue is near the C-terminus of the molecule, in an area not well defined in the electron density map, so such motion is possible but not yet proved. This particular interaction may not be of great importance, as the enzyme lacking both valine 124 and serine 123 still has substantial catalytic activity. (No consideration has been given here to other possible tautomeric forms of the bases.)

Behind and somewhat below the plane of the pyrimidine ring is phenylalanine 120, with the plane of its ring at an angle to that of the base. This packing arrangement is reminiscent of the herringbone pattern commonly found in the crystal structures of aromatic ring compounds. (The analogy should not perhaps be pushed too far, for the pyrimidine can be reduced to the dihydro compound without marked change in its ability to interact with the enzyme.) In front of the ring is valine 43, which, with phenylalanine 120, forms a groove into which the pyrimidine ring appears to go (see also Figure 4B). Positions 5 and 6 on the base are accessible to solvent and not in contact with the surface of the enzyme, according well with the fact that pyrimidines substituted in positions 5 or 6 still interact strongly with the enzyme.

In Figures 5 and 6 the sugar residue is shown in the *anti*conformation with respect to the base, as expected from the structures of the free nucleotides (Haschemeyer and Rich, 1967). The hydrogen bond to N3 of histidine 12 is easily formed from the 2' OH of the sugar. N1 of histidine 12 is bonded to a backbone carbonyl oxygen atom. The geometry of histidine 12 is thus fixed, and N3 can either extract a proton from, or donate one to, the 2' oxygen as required in the various steps of the catalytic mechanism. Note, however, that, in the actual binding of the product 3'-CMP, the NMR data of Meadows et al. (1969) show that both histidine 12 and histidine 119 are protonated at neutral pH. Thus the H bond to the 2' OH would not be formed, as shown in Figures 5 and 6. Recent interpretation of the X-ray electron-density maps of this complex shows that both histidine

FIGURE 6 Stereodiagrams of the binding of 3' CMP to ribonuclease-S. A. α -carbon atom chain (different view from Figure 4A) with inscribed box and coordinate axes— Y, vertical; X, horizontal. The arrow shows the viewing

direction for the pair below. B. Contents of the box shown in A. The same coding scheme is used as in Figure 4, except that the 3' CMP molecule is stippled to distinguish it clearly from the protein.

12 and histidine 119 appear to be hydrogen bonded to the phosphate group, and that the sugar hydroxyl group serves as the donor to the side-chain carbonyl oxygen of asparagine 44. The oxygen of glutamine 11 may be involved in holding the attacking water molecule in the hydrolytic step of catalysis.

At the present stage of the X-ray work, histidine 119 is not clearly defined, and is shown merely as being near the phosphate group in Figures 5 and 6. On the opposite side and a little above is lysine 41. Both of these nitrogen-containing groups are potentially near the phosphate group, but they are sufficiently flexible to allow considerable latitude in the exact geometry of their interaction. For the same reason, their role in the catalytic mechanism is difficult to specify in detail from purely steric considerations. Rotation about the $C\alpha$ - $C\beta$ bond puts the imidazole ring in a position in which a hydrogen bond can be established between aspartic acid 121 and one N of the ring, and the other is close to the 5' oxygen of the leaving nucleotide in a dinucleotide substrate. The X-ray evidence with ribonuclease-S for such a convenient position is unfortunately weak.

Because of the shape and nature of the base binding site,

FIGURE 7 The purine nucleotides containing adenine and formycin, with the conformation indicated. They are shown in the same orientation as the pyrimidine nucleotides in Figure 5. The arrows represent possible hydrogen bonds to or from the protein groups shown in Figure 5.

one might expect adenine-containing nucleotides to bind in the same way as pyrimidines. In Figure 7, it can be seen that, if so, the sugar residue would be moved about 3 Å away from the position it has with pyrimidine nucleotides. No interaction with histidine 12 or lysine 41 would be possible, and the relation to histidine 119 would be markedly changed. Purines do bind to the enzyme and act as inhibitors, but none have so far been found to bind in the pyrimidine site. Recent studies by W. Carlson (unpublished) indicate that 3' AMP is bound above and to the left (cf. Figure 6) of the pyrimidine site in ribonuclease-S, which would force histidine 119 out of the position in which it is shown in Figure 4B. The precise mode of binding has not yet been established, but it is assumed that this is also the site of binding of the second nucleotide in a dinucleotide substrate.

Polymers of the purine analogue formycin are exceptional, as reported by Ward et al. (1969). Surprisingly, these polymers are very good substrates for ribonuclease. Ward and Reich (1968) have also shown that the nucleotides have the syn conformation. If so, the base can go into the binding site "backward," as shown in Figure 7. The fit is close to that of a pyrimidine, with the C'_1 atom of the sugar in almost exactly the same position in the two cases. The glycosidic bond direction is, however, distinctly different, and a change in the ribose conformation would be required to put the 2' OH close to histidine 12. There appears to be sufficient flexibility in the molecule for the accommodation of such a change.

The observed geometry of the principal nucleotide binding site in ribonuclease thus appears to fit the known requirement for a pyrimidine base rather nicely and to explain the lack of action on the normal purine nucleotides. If only

the three-dimensional structure of the protein were known, however, and no information on the location of the active site were available, it seems most unlikely that one could have properly located the pyrimidine binding site. This difficulty is emphasized by present attempts to define the binding site for the second nucleotide on the other side of the susceptible bond in an RNA chain. In spite of the evidence of Carlson and Tsernoglou (unpublished) on the approximate location of the purine site, the bonding details are not obvious on inspection of the model. The substrate specificity of this site is much less than that of the pyrimidine site, as almost any substituent in a pyrimidine-containing diester will be hydrolyzed. There are rate differences of more than three orders of magnitude, however, depending on whether the second ester position is represented by a methyl group or a purine nucleotide. Some interaction of this part of an oligonucleotide ligand must be postulated. Direct crystallographic study of substrate binding is not possible, as the enzyme is catalytically active in the crystal lattice and diffusion limitation over distances of hundreds of microns is too severe (Doscher and Richards, 1963).

The recent elegant studies of Jardetsky and his colleagues on the NMR spectra of ribonuclease-A, ribonuclease-S, and some nucleotide complexes complement and extend the X-ray structure information. The work has been specifically directed to the four histidine residues: 12, 48, 105, and 119. Histidine 105 is a normal, freely accessible residue unconnected with enzymic action (Roberts et al., 1969b). Histidine 48 is related to some conformational perturbations in the protein, but is not directly connected with activity. Histidine 12 and histidine 119, however, are markedly affected by the binding of nucleotides (Meadows et al., 1969). The structural conclusions made on the basis of these extensive NMR studies concerning the probable conformation and environment of the nucleotides are in gratifying agreement with the proposals put forward from the X-ray studies (Allewell, 1969). In addition, the direct involvement of histidine 119 has been much more definitely shown in the NMR work.

The detailed mechanism of action of ribonuclease has been the subject of much speculation. The proposals, roughly in order, have been by Findlay et al. (1962), Witzel (1963), Wang (1968), Hammes (1968), and Usher (1969). The most recent entry is by Roberts et al. (1969b). These authors discuss briefly the earlier ideas and the recent work on phosphate ester hydrolysis, in particular that of Westheimer and his associates. The phosphate ester group goes through a pentacoordinate intermediate during the course of hydrolysis. This transition-state complex is represented by trigonal bipyrimid, on which entering or leaving groups must occupy the apical positions. In the "linear mechanism," the entering and leaving groups are both apical, and no difficulty arises. If the geometry requires a potential leaving group to be equatorial, a process of "pseudorotation" must take place to put it in an apical position. Both the linear and pseudorotation mechanisms are possible and known in model systems. Roberts et al. (1969a) conclude that, on the basis of present structural evidence (both X-ray and NMR) and the clear involvement of two histidine residues, the linear mechanism is applicable in ribonuclease. Their summary diagram is shown in Figure 8, which outlines the hydrolysis of a dinucleotide. In the first, or depolymerization, step, the diagram implies a linear mechanism when the attacking alkoxide formed from the ribose 2' OH is opposite the leaving 5' O of the next nucleotide. In the second, or hydrolytic, step, the diagram shows the incoming water molecule opposite the leaving 2' O in the

FIGURE 8 Possible mechanism for the catalytic action of ribonuclease. (Reprinted from Roberts et al., 1969a.)

910 RECOGNITION AND CONTROL AT THE MOLECULAR LEVEL

cyclic phosphate ring of the intermediate compound. This may or may not be true. The X-ray data are ambiguous. The kinetic data of Usher (unpublished) on various nucleotide derivatives point to adjacent attack and the subsequent involvement of pseudorotation.

In this example, there is no evidence for the production of an obviously strained substrate conformation. Indeed, the conformational flexibility of the substrate and at least parts of the enzyme make it difficult to establish a geometryrequiring strain. In this sense, the mechanism is quite different in character from that proposed for lysozyme by Blake et al. (1967).

Summary

At close to atomic resolution, the structures of a rapidly increasing number of proteins are becoming available from X-ray diffraction studies. Complexity in detail is still the order of the day. Generalizations, other than those assumed for many years, are so far elusive. Studies of stable complexes of these proteins with small ligands are generally possible. Detailed postulates of enzymic mechanisms can be developed. The origin of specificity, both strict and partial, begins to appear. Although the over-all binding energy for the interaction of a ligand and a protein may frequently be nonpolar association caused by the properties of water, the specificity will be provided by steric repulsion and by a combination of directional polar interactions, such as hydrogen bonds. These latter interactions, in effect, make incorrect associations less favorable energetically, rather than correct associations more favorable.

A binding site on ribonuclease has been identified, and the reasons for its specificity seem clear. Through adjustable interactions, the site can handle uracil or cytosine nucleotides equally well, but it discriminates against adenine- and guanine-containing nucleotides. These purine compounds bind at a different location on the enzyme. The appetite is whetted for details of the much more involved interaction sites that must exist in the enzymes concerned with the synthesis and functional control of proteins and nucleic acids, and the even more remote possibility of explaining specificity in cellular adhesion.

80 Assembly of Ribosomes

MASAYASU NOMURA

EVERY INVESTIGATOR in biological science knows that the living cell is not merely a random mixture of many molecules dissolved in certain media and surrounded by a membrane, but that it has a highly developed organization. The cell has many different kinds of subcellular structures, called organelles, and many of the major cellular functions are carried out by such organelles in a highly efficient, orderly, and regulated way. For example, cellular energy production is carried out by the mitochondria; and the translation of genetic information, i.e., protein synthesis, by the ribosomes. In addition, the cytoplasmic membrane itself is an organized structure with which several important functions are associated. In order to study the mechanism of cellular functions, one must first understand the structure of its organelles. The complexity of the structures has provided a great challenge to biochemical investigators. In this article, our recent work on one such organelle, the ribosome, is summarized. Specifically, we describe how we are approaching the two major problems encountered in such studies: first, elucidation of the structure of the organelle and its relationship to function and, second, the mechanism of assembly of the completed structure from its component molecules.

Gross structure and function of the ribosome

The gross structure of the *E. coli* ribosome is shown in Figure 1. There are two subunits of unequal size, the 50S and 30S subunits (S = Svedberg unit $\times 10^{13}$). These two particles join under suitable conditions to make a 70S particle, which is the functioning unit in protein synthesis. As described by B. Davis in this volume, one of the major functions of the 30S ribosomal subunit is its role in polypeptide-chain initiation. By itself, the 30S subunit is able to bind a special tRNA (formylmethionyl tRNA_F or fMettRNA_F) in response to a messenger RNA (mRNA) containing an initiator codon and, in the presence of several protein factors (initiation factors), the initiator codon (the trinucleotides AUG and GUG) signals the ribosome where to begin translation of the mRNA. A second function of the 30S subunit is to bind other aminoacyl tRNAs in response to mRNA; this function requires the participation of the 50S subunit. The 50S subunit also catalyzes the formation of the actual peptide bond. It has been shown that the "enzyme" responsible for this activity, peptidyl transferase, is an integral part of the 50S subunit. There are several other reactions catalyzed by the ribosome, including translocation and chain termination; these are also discussed by B. Davis elsewhere in this volume. In our routine assays, we analyze the over-all activity of the 30S subunit by measuring the rate of polypeptide synthesis directed by either synthetic or natural mRNA in the presence of the 50S subunit. Conversely, the over-all activity of the 50S subunit can be determined by measuring the rate of polypeptide synthesis in the presence of the 30S subunit. There are several other functional assays available to us. For example, the binding of tRNA directed by various mRNAs can be used to assay a more specific functional capability of the 30S ribosome preparation.

From what we know about the function of the ribosome, we can draw the following picture: the two ribosomal subunits, either independently or together, bind many com-

FIGURE 1 Gross structure of E. coli ribosomes.

MASAYASU NOMURA Laboratory of Genetics, University of Wisconsin, Madison, Wisconsin

ponents-mRNA, various aminoacyl tRNAs, several nonribosomal protein factors-and somehow assure the proper interaction of all these components for the efficient and accurate synthesis of proteins. The fine details of this picture must still be filled in, and it is clear that this requires an equally detailed description of ribosomal structure. Our knowledge of this subject is still quite elementary (Figure 1). We know that each ribosomal subunit consists of about two-thirds RNA and one-third protein (Tissières and Watson, 1958). The 30S subunit contains one 16S RNA molecule and about 20 different proteins (Kurland, 1960; Traut et al., 1967; Hardy et al., 1969); the 50S subunit contains one 23S RNA molecule, one 5S RNA molecule, and about 30 or more different proteins (Kurland, 1960; Brownlee et al., 1967; Kurland, personal communication). The proteins contained in the 30S subunit have been separated and purified. Analysis of their amino-acid compositions, peptide fragments after trypsin digestion, and molecular weights has convincingly shown that these proteins are chemically different from one another. (Traut et al., 1967; Craven et al., 1969; Fogel and Sypherd, 1968; Kaltschmidt et al., 1967). One problem that has emerged in these studies is concerned with identification of all the separated proteins from a given ribosome preparation as genuine ribosomal components rather than tightly bound contaminants. The problem can perhaps be solved only by the demonstration of a functional requirement for each of these protein components.

Complete separation and chemical characterization of the 50S ribosomal proteins have not yet been achieved.

Approaches to study the structure and function of the ribosome

The complex structure of the ribosome must reflect the highly organized and sophisticated functions it carries out in protein synthesis. Our problem is how to study this complicated structure and to find its relation to the function of the ribosome. In analogy to studies on the relationship between structure and function of enzyme molecules, effects of specific chemical modification on ribosome activity have been studied in the past. However, identification of the modified components responsible for the inactivation was difficult. Similarly, studies on mutants with altered ribosomal functions gave only limited, although useful, information on the structure-function relationship; the major limitation to this approach was again the difficulty encountered in identifying the altered ribosomal components. Clearly, then, the primary limitation in all these studies has been the lack of an assay for the function of each of the ribosomal components.

One obvious way to assay the functional role of a component is to dissociate the ribosome into its molecular constituents, separate these, and then reconstitute the ribosomal particles from the fractionated components to see if a given component is required for the reconstitution of the active ribosome. We have attempted and succeeded in this approach, although to date we have been able to reconstitute only the 30S ribosome (Traub and Nomura, 1968a).

Reconstitution of 30S ribosomal subunits from RNA and proteins

The standard method of reconstitution that we have worked out is described in Figure 2. The components of the system are purified 16S RNA and a mixture of ribosomal proteins obtained from purified 30S ribosomes; the necessary conditions include appropriate salt concentration, pH, and incubation temperature (Traub and Nomura, 1969). No other components are required. The reconstituted 30S ribosomes have been shown to be identical to the original intact 30S ribosomes with respect to sedimentation properties, protein composition (Figure 3), and the several functional abilities examined (Traub and Nomura, 1968a). Thus, at least in this in vitro system, the remarkably complex 30S ribosomal structure can be spontaneously self-assembled. One can conclude that all the information needed for correct assembly is contained in the structure of its molecular components and not in some other nonribosomal factors.

With this reconstitution system available, one can now perform unambiguous identification and functional analysis of all the essential components of the 30S subunit. We have

FIGURE 2 The standard procedure for reconstitution of 30S ribosomal subunits.

separated and purified each of the proteins contained in the 30S subunit. Altogether, we have isolated 19 major components as pure proteins (Nomura et al., 1969). After having obtained these components, we asked whether the 19 proteins comprise all the essential 30S ribosomal proteins. To answer this question, we performed the reconstitution, using the 19 purified proteins together with 16S RNA, and compared the degree of reconstitution with that obtained by using unfractionated proteins. We found that the efficiency of the reconstitution was only about half of that obtained with the unfractionated proteins (Nomura et al., 1969). It is possible that some essential components are lost during the fractionation. Nonetheless, the fact that reconstitution could be achieved with even this efficiency encouraged us to begin investigating the functional roles of these separated protein components.

FIGURE 3 Polyacrylamide gel electrophoresis of the proteins of the original 30S particles, A, and the reconstituted 30S particles, B. Some bands represent more than one protein, and altogether about 20 proteins are found in the 30S particle. (From Traub and Nomura, 1968a.)

Mutationally altered ribosomes

The first protein we studied in detail is the one responsible for sensitivity or resistance to the antibiotic streptomycin (Sm). It is known that Sm inhibits bacterial growth by inhibiting protein synthesis (for reviews on Sm actions, see Jacoby and Gorini, 1967; Weisblum and Davies, 1968). Two major effects of Sm have been observed in vitro in systems that synthesize protein: (1) Sm inhibits protein synthesis directed by natural mRNA, such as RNA from phage f2 and, to a lesser extent, that directed by certain synthetic mRNAs, such as poly-U (polyphenylalanine synthesis); (2) Sm causes misreading of synthetic mRNA. For example, poly-U normally stimulates the incorporation of phenylalanine into polypeptides, leading to formation of polyphenylalanine. In the presence of Sm, this "normal" incorporation is partially inhibited and, instead, poly-U stimulates the incorporation of leucine, isoleucine, tyrosine, and serine into polypeptide products. This latter observation is presumably related to the fact that Sm can suppress amino-acid requirements phenotypically in certain mutants of E. coli.

It is known that both in vitro effects of Sm are abolished or greatly reduced in cell-free systems when 30S ribosomes from Sm-resistant strains are used. Therefore, the site of action of Sm is the 30S ribosomal subunit. It has been postulated that Sm interacts with the ribosome to cause a distortion of its structure, which results in frequent violation of the codon-anticodon rule, leading to the observed misreading of mRNA in vitro and the suppression of mutational effects in vivo. It is clear that the component altered by the Sm-resistance mutation is important in the ribosome functions of protein synthesis and in controlling accuracy of translation of the genetic message. Using the reconstitution technique, we have identified this protein.

We first showed that the component altered by the mutation is in the protein fraction of the 30S subunit and is not the 16S RNA (Traub and Nomura, 1968b). The 30S particles reconstituted with the use of the protein from a resistant mutant and RNA from a sensitive strain were resistant to streptomycin in a cell-free, protein-synthesizing system, whereas the reverse combination produced 30S particles sensitive to streptomycin. We then purified 30S ribosomal proteins from both streptomycin-sensitive and streptomycin-resistant bacteria, and systematically substituted single proteins from a resistant strain into a mixture of proteins from a sensitive strain. We then assayed these various reconstituted ribosomes for their in vitro response to streptomycin (Table I). In this way, we have shown that the origin of a single protein (P10) determines the sensitivity of the entire 30S ribosomal particle to the inhibitory action of streptomycin, its sensitivity to streptomycin-induced misreading, and its ability to bind the antibiotic (Ozaki et al., 1969).

 Identification of P10 as the Protein Altered by the Mutation to Streptomycin (Sm) Resistance

s, derived from Sm-sensitive cells; r, derived from Sm-resistant cells.

 Σ Pi-P10, a mixture of 30S ribosomal proteins other than P10. H³-DHSm, H³-labeled dihydrostreptomycin.

This is a summary of experimental data published by Ozaki et al. (1969).

We then studied particles that do not contain this protein. In the absence of P10, 16S RNA and other 30S ribosomal proteins can still assemble into a particle sedimenting at 30S. The P10-deficient particles thus produced were found to have several interesting properties. Under the conditions used for the assays, the P10-deficient particles had a high activity when a synthetic messenger RNA, poly-U, was used as a template, but their activity was very weak when directed by RNA from a natural source. It is known that a special initiation mechanism is required for in vitro polypeptide synthesis directed by natural mRNA (see the article by Davis in this volume). In fact, it was shown that P10-deficient particles are very weakly active in this initiation function (Ozaki et al., 1969).

Another unique feature of the P10-deficient particles is related to the misreading of poly-U induced by Sm. A drastic decrease in Sm-induced misreading relative to the normal reading of poly-U was observed with these particles. As is described below, P10 is the only protein, out of 19 proteins examined, which showed such a decrease. Surprisingly, the frequency of error in translation with P10deficient particles was very much reduced, not only in the presence of streptomycin, but also in the presence of other antibiotics, ethyl alcohol, or high concentrations of Mg++, all of which are known to induce translational errors. In fact, these 30S ribosomal particles that are deficient in P10 are able to read synthetic mRNA more accurately than can 30S ribosomal particles containing that protein, even in the absence of error-inducing agents. These observations suggest that the P10 protein has a unique function that influences error frequency in the information-transfer process.

The success of this study indicates the usefulness of such an approach. The isolation of mutants with altered ribosomes should provide considerable insight into the relationship between structure and function.

Functional analysis of 30S ribosomal proteins

We have performed functional analyses similar to those used with P10 on the remaining proteins (Nomura et al., 1969). The basic approach is to perform the reconstitution, omitting one protein, and then to ask whether physically intact 30S particles are formed and, if so, whether they are active in several available functional assays. We determined physical intactness of the particles by analyzing their sedimentation behavior by sucrose gradient sedimentation analysis. The protein-deficient particles were then examined for their activities in several known 30S functions. The following assays were routinely performed: (1) incorporation of phenylalanine into proteins directed by poly-U; (2) Sminduced misreading of poly-U; (3) phenylalanyl tRNA binding directed by poly-U; and (4) binding of the initiator tRNA, formylmethionyl tRNA, directed by the triplet AUG. From such analyses we have obtained considerable information; Table II summarizes the effects of the omission of each of the 19 proteins on the gross physical assembly and the functional capability of the particles. In the Table, a given protein is indicated as being required for function when significant reduction of activity is observed in any of the assays used.

The results of sedimentation analysis of the protein-deficient reconstituted particles have allowed division of the proteins into two groups. One comprises proteins which apparently are not essential for the self-assembly reaction in vitro, and the other includes proteins (P4a, P4b, P5, P8, and P9) which are essential for the formation of particles with a sedimentation coefficient of 30S. Particles formed by the omission of one of these latter proteins either moved with a sedimentation coefficient of 20S to 25S, rather than 30S, or sedimented as a heterogeneous mixture of variously sized particles. In these cases, it appears that the particles formed are also deficient in several other proteins, even though these were present in the reconstitution mixture. Thus, the presence of some proteins is essential for the binding of other proteins, which suggests that the assembly process is cooperative.

Although detailed analyses of the protein-deficient reconstituted particles are still under way, the results obtained so far have allowed us to draw several conclusions.

1. Most of the proteins, except P1 and P3a, are clearly required for the intact functional activity of the ribosome. Omission of any of these proteins caused decreases in some or all of the functional activities assayed. Thus, these 17

TABLE II Nomenclatures of 30S Ribosomal Proteins and Tentative Conclusion on Functional Requirements

Our Code	Kurland's Code	Requirer Assembly	nent for Function	Note

Symbols for assembly requirement: +, omission of the protein produces particles sedimenting at 20–25S; \pm , omission of the protein produces a 27–28S particle: –, the protein is not required for formation of the 30S particle.

Symbols for functional requirement: (++), strong requirement presumably because of requirement in the assembly reaction; ++, strong requirement; +, partial requirement; -, no requirement demonstrated; (\pm) , weak effect on the initiation reaction.

For details, see the text.

proteins are not irrelevant contaminating proteins and, in all likelihood, must represent genuine ribosomal components. On the other hand, we have not yet reached any definite conclusion with respect to P1 and P3a. They might be not genuine ribosomal proteins, but merely proteins tightly bound to the 30S ribosomal particles. Alternatively, it is possible that they are ribosomal proteins the functions of which cannot be detected by the activity assays we have used.

2. Proteins P4a, P4b, P5, P8, and P9, which are essential for physical assembly, were also shown to be essential in almost all the functional assays employed. Particles lacking anyone of these proteins are devoid of function. Therefore, "intact" physical assembly is apparently prerequisite to the appearance of 30S ribosomal functions.

3. Some other proteins, which apparently are not required for assembly, were also shown to be required for some or most of the ribosomal functions. Conversely, any of several known 30S ribosomal functions studied were shown to be affected by omission of any of a number of proteins. Many of the 30S ribosomal functions seem to require the presence of more than one protein component, so one can say that the 30S ribosomal proteins function cooperatively.

4. Two proteins, P10 and P7, were found to be of special interest with respect to translational fidelity. As mentioned above, P10 is the protein altered, as a result of mutation, to streptomycin resistance, and the P10-deficient particles showed a great decrease in the extent of translational errors induced by various agents. On the other hand, the particles reconstituted in the absence of P7 showed a dramatic increase in a misreading of the poly-U message. Again, out of 19 proteins examined, P7 is the only protein that showed such a marked increase in misreading. Thus, these two proteins apparently act in opposite ways; the presence of P10 decreases fidelity and that of P7 increases fidelity. Mutational alterations in these proteins may confer various additional specificities in the function of these proteins in translational fidelity. It is conceivable, therefore, that a sophisticated and subtle control of translational fidelity is effected genetically, as well as physiologically, by these two proteins.

Functional analysis of 16S ribosomal RNA

The functional role of ribosomal RNA has long been a mystery. The availability of the 30S reconstitution system now permits us to investigate this problem.

First, we have found that RNA must be present for the assembly reaction to occur. In the absence of 16S RNA, no soluble particles resembling the ribosome are formed. Thus, the situation is quite different from the assembly of the TMV particle, in which case particles resembling mature virus are formed from protein subunits even in the absence of viral RNA. Moreover, 16S RNA from yeast or 18S ribosomal RNA from rat liver cannot replace E. coli 16S RNA to make particles sedimenting at 30S. Only very heterogeneous nonspecific aggregates or insoluble particles are formed under these circumstances (Traub and Nomura, 1968a). The presence of some specific RNA is, therefore, essential for assembling ribosomal proteins into a particle sedimenting at 30S. Specifically, then, the base sequence of the RNA should be an important factor. To test this, we initiated a series of experiments in which we performed reconstitutions, using 16S RNA from one species of bacteria and 30S ribosomal proteins from a distantly related species (Nomura et al., 1968). We found, in fact, that such "artificial" ribosomes are, in many cases, as active as the respective homologous RNA and protein combinations. Although 16S RNAs from these different bacterial species have some portions of their base sequence in common, a large part of this sequence is different. We conclude that, although there is definitely a specificity requirement of the RNA, such a requirement is not absolute. It appears that only certain small regions of 16S RNA are directly involved in the specific interaction with the ribosomal protein. Identification of such regions and the nature of the interactions are the principal goals in the study of ribosomal assembly.

As mentioned above, chemical modification is one approach to the question of the relationship between the structure and function. With the reconstitution technique available, it is now possible to identify the altered components in the inactive ribosomes treated with various specific reagents. It is also possible to modify separated components individually, and then to examine their functional alterations in the reconstituted ribosomes. Using such an approach, we have studied nitrous acid modification of RNA and of ribosomes. We have found that amino groups in the bases of 16S RNA are important but are probably primarily required for the assembly reaction (Nomura et al., 1968). In conclusion, the only positively identified function of 16S RNA to date is its role in the assembly of the ribosomal particle. The question of whether ribosomal RNA is directly involved in any of the known ribosomal functions must await further studies.

Assembly of 30S ribosomes studied in vitro

The 30S ribosome reconstitution system has been used to study the mechanism of the self-assembly reaction (Traub and Nomura, 1969). After we had defined the optimum conditions for reconstitution with respect to ionic strength, Mg^{++} concentration, pH, and temperature, we studied the kinetics of reconstitution at different temperatures. Two major conclusions were obtained: (1) the reaction is first order with respect to formation of active 30S ribosomes, and (2) the rate of reaction is strongly dependent on the temperature of incubation and has an Arrhenius activation energy of 38 Kcal/mole. The first conclusion was obtained by our following the time course of the reaction and examining the effect of dilution of the incubation mixture on the kinetics of the reaction. Thus, although the over-all assembly reaction involves as many as 20 reactants, the ratelimiting reaction appears to be unimolecular.

The rate-limiting step in the assembly process could occur at any time before the formation of functionally active 30S ribosomes, i.e., only after none or some proteins are bound to the RNA, or after all are bound. In any case, our observations would have been the same. Although we have not yet rigorously identified the intermediate undergoing the unimolecular structural rearrangement reaction, we have obtained evidence that the intermediate particle is a ribonucleoprotein particle deficient in certain proteins. As mentioned above, the assembly reaction is extremely slow at low temperatures. We have found that, under such conditions, a particle that has some, but not all, of the proteins accumulates. We were able to isolate such a particle, activate it by warming the solution, and observe the relatively instantaneous binding of the rest of the proteins, with consequent formation of a completed ribosome. In this way, we could elucidate the general nature of the "pathway" of the self-assembly reaction: rapid binding of some of the proteins to the RNA, a slow structural rearrangement of this intermediate with the use of thermal energy, then rapid binding of the rest of the proteins.

We have already seen that the presence of one of a few proteins (P4a, P4b, P5, P8, and P9) is essential for some other proteins to bind. Systematic studies with separated proteins should soon reveal more details of the pathway of the selfassembly reaction, and may even give some insight into the nature of the geometrical relationship of the different molecular components.

Assembly of ribosomes in vivo

After obtaining all this information on assembly in vitro, one must ask the obvious question: Are these same principles operating in the living cell? The problem of ribosome biosynthesis in vivo was being studied long before in vitro assembly was even seriously considered. Intricate experiments were performed in which short pulses of radioactive RNA precursor compounds were administered to growing bacterial cells, and their flow into mature ribosomes was followed (McCarthy et al., 1962; Mangiarotti et al., 1968; Osawa, 1968). In this way, several classes of precursor particles were postulated, but their characterization was difficult in most cases. It is clear that such an approach has obvious limitations in providing the detailed mechanism of in vivo ribosome assembly. Another approach to this problem is to isolate mutants defective in the assembly of ribosomes and to identify the nature of the defects and the genes responsible for them. In analogy to mutants defective in biosynthetic pathways of small molecular weight metabolities, some of these mutants may accumulate intermediate particles in ribosome assembly. In fact, several bacterial mutants have been isolated previously which show an accumulation of some 50S "precursor" particles (Lewandowski and Brownstein, 1966; MacDonald et al., 1967), but the block in the biosynthetic pathway was not complete, and conditions for "precursor" accumulation were not defined. Moreover, no systematic method to isolate these ribosome-assembly, defective mutants has been available.

In order to confirm our in vitro results, we decided to use a genetic approach. As mentioned before, in our detailed study of the in vitro assembly reaction, we observed the remarkable dependence of the rate of reaction on temperature. The conversion of the inactive intermediate particle to an active configuration, described above, is almost infinitely slow at 10° C or below, resulting in the accumulation of these particles. Thus, the assembly reaction is inherently easier at higher temperatures in this in vitro system. If the biosynthesis of ribosomes in vivo also involves essentially the same principle, then many mutational defects, either in ribosomal structural components or in extra-ribosomal components affecting the assembly process, should manifest themselves more clearly at lower temperatures. Such assembly-defective mutants should be viable at high temperatures, but unviable at lower temperatures; that is, they could be isolated as cold-sensitive mutants. This reasoning proved to be correct. We have isolated a large number of coldsensitive mutants of E. coli, a significant fraction of which appear to be defective in ribosome assembly (Guthrie et al., 1969). We have already identified three distinct classes of particles, from three different mutants, which accumulate in cells grown at 20° C (Table III). Two of these particles appear to be 50S precursors, and the third is a 30S precursor. We have done some preliminary studies on the characterization of these particles, as well as on their formation and fate under various conditions both in vivo and in vitro. In addition, we are currently isolating many more mutants and are performing genetic analysis of the various mutants in the hope of obtaining much-needed information on the genetic organization and control of the ribosome and ribosomal assembly.

Summary

Several years ago, our knowledge of ribosome structure and its relation to function was meager. The success of the reconstitution of 30S ribosomes from their molecular components has provided the means to attack these problems. Coupled with biochemical and genetic techniques, the reconstitution technique has now started to produce much information on the structure, function, and assembly of the 30S ribosome. This situation makes us optimistic that even more complex cellular structures, including nerve-membrane structures, will some day also be understood on a truly molecular level.

81 Recent Advances in

Understanding Ribosomal Action

BERNARD D. DAVIS

THREE YEARS AGO in Boulder Rich (1967) reviewed the state of our knowledge of protein synthesis. It was certain by then that a linear messenger RNA (mRNA) molecule is simultaneously translated by a number of ribosomes, on each of which the growing polypeptide chain is covalently attached to a transfer RNA (tRNA) molecule, which in turn is noncovalently held on the ribosome. There were also good grounds for inferring that the elongation of the polypeptide involves its shuttling back and forth between two sites, as described below. Finally, the analysis of the genetic code, by the groups of Nirenberg, Ochoa, Brenner, and Khorana, revealed that the ribosome moving along the

920 RECOGNITION AND CONTROL AT THE MOLECULAR LEVEL

BERNARD D. DAVIS Bacterial Physiology Unit, Harvard Medical School, Boston, Massachusetts

mRNA reads its sequence of nucleotides in units of three: each such trinucleotide codon pairs with the complementary trinucleotide anticodon of a particular aminoacyltRNA (aa-tRNA) and thus specifies the addition of a particular amino acid.

Further work has provided strong support for the twosite shuttle mechanism. The studies have employed two of the classic approaches of biochemistry: fractionation of the system, and the use of compounds (in this case, mostly antibiotics) that inhibit the process at various stages. The coherence of the results obtained has generated considerable confidence in this model (but does not exclude the possibility, for which there is suggestive evidence, of one or more additional sites for prealigning aa-tRNAs). In the two-site model, the process of adding an amino acid to the nascent chain can be described in terms of a cycle of three steps (Figure 1). In the first, or *recognition*, step, the entering moved from the A to the P site; in this major shift, the donor tRNA is displaced from the P site, the A site is freed, and the movement of the mRNA brings the next codon up to that site.

Summary of recent advances

In addition to verifying the two-site model, work of the past three years has also revealed a number of significant new features of ribosome structure and function, which I now review briefly. Most of this work is documented in a recent Cold Spring Harbor Symposium (Cairns, 1969) and has been reviewed in more detail by Lipmann (1969) and by Lengyel and Söll (1969).

DIRECTION OF TRANSCRIPTION, TRANSLATION, AND MRNA DEGRADATION It has been known for some time

FIGURE 1 The two-site model for protein synthesis on the ribosome.

aa-tRNA is bound to the "A" (aminoacyl) site of the ribosome, while the polypeptidyl-tRNA is held in the "P" (polypeptidyl) site. In the next step, *peptidyl transfer*, the polypeptide is shifted from its tRNA to the amino group of the amino acid on the adjacent tRNA, thus becoming one residue longer. The cycle is completed by the *translocation* reaction, in which the peptidyl-tRNA, still complexed with its complementary codon in the mRNA, is

that the synthesis of mRNA (transcription) and its translation both proceed in the $5' \rightarrow 3'$ direction. In bacteria, in which mRNA turnover is rapid, Morikawa and Imamoto (1969) and Morse et al. (1969) have recently shown that mRNA degradation takes place in the same direction. Moreover, further evidence indicates that while the head end of a growing mRNA molecule is being transcribed on the DNA the tail end is simultaneously being destroyed, and in between as many as 100 or more ribosomes are closely packed on the mRNA and evidently protect it from destruction (Figure 2). In this respect, protein synthesis in bacteria differs from that in eukaryotic cells, in which most mRNA clearly cannot remain attached to the nuclear DNA because it is translated in the cytoplasm.

FIGURE 2 Schematic view of the simultaneous formation, translation, and degradation, in the same direction, of the mRNA chain. E: Enzyme (RNA polymerase) transcribing DNA.

PROTEIN COMPOSITION OF RIBOSOMES It is now generally agreed that the 30S ribosomal subunit contains 19 or 20 different protein molecules; the 50S subunit, about 30. Moreover, no protein is represented more than once; hence the entire surface of the ribosome is highly differentiated. Surprisingly, some ribosomal proteins have been found in fractional amounts (Kurland et al., 1969; Traut and Delius, 1969), but the significance of this observation is not clear: it may mean either that the ribosomes of a cell are heterogeneous in their protein composition, or that the process of purification may have partly removed certain proteins.

RIBOSOME RECONSTITUTION In an important development, Traub and Nomura (1968) have succeeded in reconstituting fully active 30S subunits from their separated RNA and proteins. The separation requires rather drastic conditions (2 M LiCl + 4 M urea), and even the proteins alone require a high salt concentration to prevent spontaneous aggregation and precipitation. The key to successful reconstitution appears to lie in allowing the proteins to reaggregate with the RNA and with one another at a high enough temperature (40° C) to permit the various molecules to shift position until they have reached the best fit.

THE INITIATING TRNA In *E. coli*, the polypeptide chain is initiated by a codon, AUG, that causes the binding not of

an aa-tRNA but of formylmethionyl-tRNA (f-met-tRNA) (Adams and Capecchi, 1966); the terminal formyl group is later deleted enzymatically from the growing chain. This feature of initiation is clearly part of a mechanism for preventing the generation of incomplete polypeptides by initiation at codons within a gene: the aa-tRNAs that these codons call for differ from both polypeptidyl-tRNA and f-met-tRNA in having a charged a-amino group; and loss of this charge, which changes the configuration of the tRNA, is evidently required before it can be accepted by the P site.

INITIATION BY SUBUNITS The construction of the 70S bacterial ribosome in the form of a readily dissociated pair of subunits (50S and 30S) has long been a puzzle. The solution was provided by experiments of Kaempfer et al. (1968) with mixtures of heavy and light ribosomes: in the course of protein synthesis, the subunits were found to exchange partners, producing hybrids of intermediate density. Moreover, Nomura and Lowry (1967) showed at the same time that in a system initiating protein synthesis physiologically, in contrast to the familiar system with synthetic homopolynucleotides as messenger, f-met-tRNA complexes with the initiating codon on a 30S subunit rather than on a complete 70S ribosome. Thus, the macrocycle of ribosome release from the reattachment to messenger involves a sequence of dissociation, formation of an initiation complex by the 30S subunit, and reassociation of the 50S subunit with this complex.

PROTEIN FACTORS In the course of ribosomal function, several protein factors are attached and detached at specific stages. 1. In the microcycle of chain extension, as Nishizuka and Lipmann (1966) have shown, three separable factors (Tu, Ts, and G) are required. 2. In the release of the completed polypeptide, Capecchi (1967) discovered that the termination codons are read not by a special tRNA but by a release protein, which directly or indirectly causes the peptidyl-tRNA bond to be cleaved. More recently, two proteins, of different codon specificity, have been shown each to have this release function (Scolnick et al., 1968). 3. The use of natural (viral) mRNA revealed that the initiation process involves three protein factors, called F1, F2, and F3 (Stanley et al., 1966; Iwasaki et al., 1968), or factors A, C, and B (Revel and Gros, 1966; Revel et al., 1968), respectively.

This multiplicity of removable proteins functioning on the ribosome suggested at first that the definitions of true ribosomal proteins and of separate protein factors might be arbitrary. This question has been resolved, however, by further work on the roles of the factors, and I wish now to consider this important development in somewhat more detail.

Role of chain elongation factors

The function of the chain elongation factors (Ts, Tu, and G) has recently been reviewed (Lipmann, 1969). These proteins are present in abundance in the cytoplasm of *E. coli*, constituting in all about 2 per cent of its soluble protein. Ts catalyzes the formation of a Tu-GTP-aa-tRNA complex, which then enzymatically binds the aa-tRNA to the ribosome in the proper position, with the utilization of energy derived from hydrolysis of the GTP. The G factor is required for translocation, which involves the hydrolysis of another molecule of GTP. The Tu factor that is bound along with a GTP is released after the hydrolysis of the latter to GDP and phosphate, and the same is probably true of the bound G factor; these factors thus appear to have only a transient attachment to the ribosome.

The antibiotic puromycin has played an important role in the development of this picture. It serves as an analogue for the aminoacyl end of aa-tRNA and has provided a useful model for the peptidyl transfer reaction. Moreover, it has been helpful in our recognizing and characterizing the translocation step, for it releases the nascent polypeptide as polypeptidyl-puromycin when the peptidyl-tRNA is in the P site but not when it is in the A site. Additional antibiotics with a well-established action on the ribosome are also listed in Table I. versible synthesis, but also to reconcile firm and highly specific attachment with freedom of movement on the ribosome surface. For example, because the specificity of binding is determined by the relatively small energy contribution of the codon-anticodon interaction, the total energy involved in the initial binding cannot be very large. After this binding, however, the energy contribution from GTP hydrolysis could be used to lock the aa-tRNA in place and thus to permit it to accept peptidyl transfer without danger of losing the incomplete chain.

Role of initiation factors

In contrast to the large supply of elongation factors in the cytoplasm, the three protein initiation factors are found in a smaller supply. Moreover, this supply is largely attached to the 30S subunits (Eisenstadt and Brawerman, 1967).

In considering the functions of the initiation factors, we must know whether these functions begin before or after the dissociation step that takes place after runoff. For a time, it was widely believed that this dissociation is spontaneous and immediate, for certain kinds of gently prepared extracts were found to contain only polysomes and subunits (Mangiarotti and Schlessinger, 1966); the 70S ribosomes observed earlier would therefore be fragmented polysomes, in which the subunits are held together by

TABLE ISpecific Actions of Various Antibiotics on the Ribosome

* A, ribosomes from cytoplasm of various animal cells; B, ribosomes from bacteria.

The amount of energy expended by the cell in protein synthesis is surprisingly large: two high-energy phosphate bonds are hydrolyzed in attaching an amino acid to tRNA, plus one in aa-tRNA binding and one in translocation. Thus, about 32 kcal are expended to create a peptide bond, the energy of which is about 3 kcal. The surplus of energy is presumably used not only to promote rapid and irre-

complexing with peptidyl-tRNA and mRNA. However, we and others have obtained several kinds of evidence that the 70S runoff ribosome is a significant and stable component of the cell. 1. A method of lysis that avoided certain artifacts yielded polysome-containing extracts of *E. coli*, in which about 10 per cent of the ribosomes were present as 70S particles (Kohler et al., 1968). 2. Under various conditions that caused accumulation of the products of runoff, by promoting runoff or preventing reinitiation, the net increment in these products appeared entirely as 70S particles and not as subunits (Kohler et al., 1968; Algranati et al., 1969). 3. Such runoff ribosomes, and also the "normal" 70S ribosomes in extracts of growing cells, could be distinguished from fragmented polysomes by their greater ease of dissociation at a low Mg^{++} concentration (Ron et al., 1968).

The unexpected constancy of the subunit concentration, in the face of a large increment in the runoff ribosomes, had the further significance of suggesting that the dissociation of runoff ribosomes in the cell might require stoichiometric complexing with a dissociation factor, present in limiting supply. Moreover, because the mixture of known initiation factors can support initiation by 70S ribosomes, and because initiation requires dissociation, this mixture should include the dissociation factor. This prediction was readily verified: the usual preparation of initiation factors, extracted by $1 \le 1000$ MNH₄ C1 from the ribosomal pellet (or from the 30S fraction), caused dissociation of runoff ribosomes (Subramanian et al., 1968) but not of polysomal ribosomes (Davis et al., 1969). This finding led to the model tor the ribosomal macrocycle depicted in Figure 3.

FIGURE 3 Model for the macrocycle of ribosome runoff, dissociation, formation of initiation complex, and chain extension (Subramanian et al., 1968). Not only the dissociation factor (DF), as depicted, but also the other initiation factors (Eisenstadt and Brawerman, 1967) are attached to the native 30S subunit and then are detached at some stage in its conversion to a complete polysomal ribosome.

Subsequent work with purified preparations of the three initiation factors, kindly provided by A. J. Wahba and S. Ochoa, has shown (Subramanian et al., 1969) that the dissociation factor is present in the F_3 (Factor B) fraction. Because this factor is known to promote the binding of natural mRNA (Revel et al., 1969; Wahba et al., 1969), it appears that complexing of F_3 with the 30S moiety of a 70S ribo-

some may cause both a decrease in its affinity for the 50S moiety and an increase in its affinity for the messenger. This linkage of functions seems reasonable, as dissociation and binding of messenger are evidently the first two steps in initiation. The other two initiation factors are known to promote the next step, the binding of f-met-tRNA by the messenger-30S complex (Revel et al., 1969; Wahba et al., 1969; Kolakofsky et al., 1969).

An unexpected further finding was that the effectiveness of the F_3 fraction in promoting dissociation can be increased severalfold by ATP or GTP, in physiological concentrations (Subramanian et al., 1969). A non-hydrolyzable analogue of ATP or GTP also proved to be effective, so it appears that the dissociation reaction does not require an input of energy. These findings raise the possibility of a regulatory response of the dissociation reaction to the "energy level" in the cell.

General conclusions and speculations

A common feature of the initiation factors and the chain elongation factors is that each factor appears to go on and off the ribosome during the addition of a single amino acid. A major difference is that the elongation factors are found largely free, but the initiation factors are largely bound to the 30S subunits; moreover, the total supply of the latter factors (assuming one molecule of each per 30S subunit) is considerably smaller. This pattern is clearly economical: the initiation factors are available for instant use, as they are stored largely on the 30S subunits; the elongation reaction, which occurs several hundred times as frequently as initiation, requires a large supply of its free factors, comparable to that of aa-tRNAs, in order to provide a high rate of contact.

Although the reason for physiological initiation by one subunit followed by the other, rather than by the whole ribosome, is not certainly known, the striking applicability of simple mechanical principles to other aspects of molecular genetics tempts one to speculate that the subunits form a clamp around the mRNA. In comparison with simple adsorption, such a mechanism could obviously result in firmer attachment without loss of ability to move during translocation.

Because the free ribosomes do not appear to play an active role in the cycle, in contrast to polysomal units and subunits, their existence in the cell requires teleonomic justification. The explanation, I suggest, may lie in the finely adjusted affinities that permit the ribosomes to dissociate at one stage in the macrocycle and to reassociate at another. For the dissociation reaction is not an all-or-none reaction, driven to completion by a large drop in free energy. Rather, it appears to be a reversible equilibrium. The optimal conditions for the succession of dissociation and association may thus require a narrow range of subunit concentration; the pool of runoff ribosomes could then provide a buffer that permits the subunit level to remain constant, despite wide shifts in the rate of protein synthesis (and hence in the level of polysomes).

Mammalian ribosomes

In eukaryotic cells, in organisms ranging from fungi to mammals, the cytoplasmic ribosomes are known to differ in a number of respects from the ribosomes of the prokaryotic bacteria: they are larger (ca. 80S); they dissociate less readily as the Mg⁺⁺ concentration is lowered; they are inhibited by a different set of antibiotics (with some overlap); and the mRNA that they translate is considerably more stable. Nevertheless, the process of chain extension similarly involves three protein factors and GTP, and the process of runoff and reinitiation similarly involves subunit exchange. However, the initiating tRNA in this system, and the initiation factors (if any), have not been identified.

We may note that evolution has handled the machinery of protein synthesis conservatively: not only is the genetic code universal, but prokaryotic and cytoplasmic eukaryotic ribosomes, despite the difference in their size, can function with some tRNAs and even with the G factor from either class of organisms.

UNSOLVED PROBLEMS Major problems for the future include definition of the structure of the ribosome (e.g., mapping the relation of the various proteins to one another and to various parts of the RNA), correlation of this structure with the sites inferred from functional studies, and analysis of the conformational changes that are associated with the various steps in ribosomal function. Of these steps, translocation is the most challenging, because it is clearly much more complex than any known enzyme reaction.

At present, there is a wide gap between the chemical studies on ribosomal proteins and the functional studies that have suggested the several sites and steps depicted in Figure 1. I hope that electron micrographs of increased resolution will help to bridge this gap, but the pictures so far available (Figure 4) suggest only a rather complex shape for the 50S subunit, with no definitely recognizable binding sites.

Several possible implications for neurobiology may be seen in these studies on bacterial ribosomes. First, as already noted, much the same mechanism of protein synthesis is found in mammalian cells—and in neurons this process is apparently important for function as well as for growth. Second, the formation of the 30S ribosomal subunit by spontaneous aggregation of its component molecules, described by Nomura in greater detail elsewhere in this volume, encourages the hope that the morphogenesis of cell membranes can also be reproduced in vitro. Finally, the extension of the study of biosynthesis to longer and longer sequences of enzymatic reactions failed to explain protein synthesis. The solution was found instead in a much more elaborate piece of molecular machinery—one in which a stable aggregate of some 50 different proteins and three RNA molecules cooperates with several transiently attached ligands, and expends considerable free energy, to provide specificity in the basically simple formation of a peptide bond. Perhaps an equally novel and elaborate machinery is involved in some of the mysteries in the development and the function of the nervous system.

As an epilogue, I wish to contrast the central role of genetics in modern biology, including the contributions of molecular genetics to our knowledge of protein synthesis, with the slight role of genetics thus far in the neurosciences. In neurophysiology, to be sure, the possibility of finding useful genetic approaches to most of the current problems seems limited, but in the developmental biology of the nervous system the prospect is exciting and has already attracted several investigators with brilliant records in molecular genetics. Moreover, genetics seems to me to have an even more definite future role in the understanding of behavior, including human behavior. We cannot pretend that the intellectual plasticity provided by the neocortex is infinite, and it would be sad if the application of the advancing science of genetics to the problems of human behavior were restricted by political considerations based on this assumption. If our increasingly complex society builds its social policies on the basis of either liberal or reactionary preconceptions about "human nature," and if this foundation does not correspond to reality, we surely will eventually pay a cruel price. If the education of students in the behavioral sciences regularly included a substantial exposure to genetics, it might help to avoid such an unfortunate development.

Summary

Recent advances in the study of the ribosome have confirmed the conclusion that the polypeptide chain adds an amino acid by shuttling back and forth between two sites, remaining always attached to the tRNA of the last amino acid added. It has also been shown that this process involves the participation of a protein factor that goes on and off the ribosome in the recognition step in each addition of an amino acid, and another that participates in the translocation step.

The process of chain initiation similarly involves transient attachment of several protein factors, which participate in the several steps of initiation: the dissociation of the runoff ribosomes into subunits; the formation of an initiation complex of the 30S subunit, messenger RNA, and formyl-

FIGURE 4 Electronmicrographs of 50S ribosomal subunits of *E. coli*, viewed from various angles (Lubin, 1968). Particles were fixed with buffered formaldehyde unless

methionyl-tRNA; and reassociation with the 50S subunit. The cell has thus developed an elaborate machinery, and expends a large amount of energy (four high-energy phosphate bonds per peptide bond formed), not only to promote speed but also to insure specificity, correct initiation, and correct termination in the translation of an RNA message into a polypeptide product.

82 Extracellular Evolution of Replicating Molecules

S. SPIEGELMAN

The gene and the concept of "self-duplication"

As a result of experiments to be described, we can, for the first time, explore certain aspects of precellular biological evolution. Before these results are detailed, it may be instructive to consider in somewhat general terms the concept of evolution and its significance for "living" and "nonliving" matter.

We begin with a discussion of the minimal conditions required for evolution and the central contributions made to this problem by geneticists at the beginning of the present century.

A necessary condition for evolution is the existence of an entity capable of "self-duplication" or "self-replication."

S. SPIEGELMAN Institute of Cancer Research, Columbia University, New York, New York

We use these terms because of their historical prevalence. They are semantically unfortunate, because they have generated a plethora of unnecessary difficulties. To some, these terms have implied that such entities must be able to function by themselves, unaided by other devices, in the production of copies. This line of reasoning led to holistic arguments that the cell was the smallest unit capable of selfduplication, in accord with pregenetic thinking, which held that the cell and its capacities to produce copies of itself were consequences of a concatenation of interlocking reactions which served to maintain the phenotypic characteristics from one cell generation to the next.

With the recognition of mutations and their implications, this view became increasingly difficult to maintain. To support it, one would have to argue that a single modification in the complex of interacting reactions so modified the whole as to maintain and transmit this unique event-a viewpoint tenable logically, but implausible practically. Further, if this view were correct, unraveling the details of the duplicating mechanism would constitute an inordinately difficult task. In contrast, the geneticists offered a more optimistic alternative. They proposed the existence of cellular entities called genes, which alone possessed the capacity of self-duplication. All cellular properties, including self-duplication, were the consequence of the autosynthetic and heterosynthetic instructive capabilities of the genetic material. The implications of the geneticists were therefore both more optimistic and more understandable; they were saying that, if we ever identify the chemical nature of the gene, and thereby gain an understanding of its mode of replication, we will have understood the essence of replication. This prediction was fully confirmed in 1953 with the announcement of the Watson-Crick model of DNA.

An operational definition of "self-duplication"

To be useful to biologists, one must extend the concept of self-duplication beyond that of copy generation. Any copying mechanism that is *absolutely* faithful has no evolutionary future and therefore serves no purpose as a biological model. Selection cannot operate on identical copies, so the potential for evolution demands variation. The existence of variants that permits selection demands a source of variability, which ultimately must come from inaccuracies in the copies. These inaccuracies can, in principle, occur either in the copying process or by modification of some of the copies. Whatever their origin, the changed copies must *retain* the capacity of replication if they are to have evolutionary consequences.

A usable operational definition of a self-duplicating entity has a similar requirement. It is important to recognize at the outset that self-duplication always involves two components. One is the entity being copied and the other is the copying machine. Essentially, we want to know which one of these two components is the *instructive* agent in the replicating process. It is conceivable that the copying machine is designed to turn out copies only of the particular entity being considered, the duplicated object serving merely as a stimulus for synthetic activity. Were such the case, the entity being copied would not be the instructive agent in the duplicating process, and any mistakes made in the copying process would not be transmitted to future generations.

By a self-duplicating entity, we mean a self-instructive agent that carries the information in its structure for its own synthesis and can transmit this information to a passive synthesizing machine, which fabricates the kinds of copies it is told to. A requirement for an operational definition of a self-instructive replicating agent is the availability of at least two distinguishable variants. Each is then given to the synthesizing machine. If the product produced is always the same and is independent of the particular entity used to initiate the synthesis, we do not have a self-duplicating object. On the other hand, if the copies generated by the synthesizing machine always correspond to the initiating variant, we have satisfied the operational definition of an object capable of self-instructive replication. We see, then, that evolutionary potential and a useful operational definition of the class of self-duplicating objects both require a source of variants.

To summarize, we define a self-duplicating—or, better, a "self-instructive replicating" (SIR)—object as one that, in the presence of a suitable synthesizing machine, possesses the following two properties: (1) at least one copy is required to get another, and (2) variants are occasionally produced and can function as instructive agents to initiate copies of themselves.

It should be noted that nothing is said about whether or not the synthesizing machine is also copied. Both situations satisfy our definition. In biological systems, the copying machines are also copied, but other devices are required for *their* fabrication, and all the information needed to synthesize these machines and other ancillary devices required must be contained in the *structure* of the self-instructive replicating object. These and other issues can be seen more clearly in terms of comparatively simple objects we consider below.

"Living" and "nonliving," "self-instructive" replicating objects

It is important to emphasize that our operational definition of self-instructive replication is not meant to provide an operational device to distinguish "living" from "nonliving" matter. In practice, it is not certain that an operational distinction is possible; we return to this question later. To make the central issue clear, it is instructive to consider some examples of objects that satisfy the two conditions specified and that are not generically derivable from what we would all accept as "living" material.

A somewhat trivial case is provided by Xerox copies in a universe of Xerox machines. One needs one copy to get another. Further, if a particular copy is modified and then fed back into the Xerox machine, the modifications will be reproduced in future copies. Of course, the permissible changes here are limited to those that can be made on paper and that can, in turn, be Xeroxed. All copying devices, however, have similar restrictions of greater or lesser complexity. This system clearly has an evolutionary potential, but of a relatively limited nature.

The Xerox example gains in interest to us, and greatly increases its evolutionary range, when we recognize that the material being copied can, in fact, contain information. In particular, this information could constitute the set of directions for making Xerox machines. We now have a potentially more interesting relation between the Xerox machine and the copies it is generating. If modifications are produced on individual copies and these modifications are, in fact, used to generate copies employed by engineers to build new Xerox machines, the consequence will be an evolution of the Xerox machines themselves. This sort of extension brings us close in principle to another class of devices, the "self-duplicating automata" conceived of by von Neumann (1966).

The von Neumann machines represent logical extensions of devices commonly found in the automatic tool-making industry. In principle, it is possible to devise a machine that can make copies of itself. Such a machine can be placed upon a pile of its component parts. The machine then selects the one required at the particular stage in the manufacture. So that the operations leading to the building of the new machine may contain no inconsistencies, the set of instructions can be put serially on a tape. In such a way, one avoids the possibility that the machine will attempt to do something physically impossible. Thus, if the machine must put a bolt in a hole, it is important that the instruction for drilling the hole precede that for the insertion of the bolt.

After the set of instructions leading to the fabrication of the new machine are finished, one will find a replica of the original machine sitting beside the old one. This is a copying device, but it does not have the essential property of transmitting mistakes, which we require of a self-instructive replicating object. Suppose, however, that, subsequent to the instructions for the fabrication of the new machine, we give another set of instructions that say, "Make a copy of me, the tape, and then transfer it to the new machine." Once this last set of instructions is completed, the newly completed machine contains the set of instructions required to fabricate the next one. We now have a self-instructive replicating device in which everything, including the copying mechanism, is copied.

Imagine that a biologist were to come upon a group of machines such as these busily engaged in making new ones. If he were a geneticist, he would look for variants in the machines (e.g., an abnormal positioning of a hole on a particular plate). Once it was identified, he would isolate it and see if the next generation made by the variant machine would, in fact, inherit the variation. If the new machine produced by the variant did not exhibit the variation, the geneticist would label it a "phenotypic" variant and would conclude that the mistake was not made in *copying* the set of instructions, but rather in *following* the instructions. If, on the other hand, the variation was, in fact, transmitted to the next generation, he would conclude that this variation was genetic, i.e., the mistake was made in copying the set of instructions transmitted to the new machine.

It should be noted that such machines could be instructed to undergo a process akin to that of recombination. Two machines could approach each other and align their tapes so that the two ends coincided. The tapes could then be compared and, if differences were found, the tapes could be cut at some point between the differences and rejoined so that each possessed a portion of the other's tape.

It seems clear that, if a geneticist carried through the kinds of operations on these machines that he does with living matter, he would identify the tapes as the genetic material. The instructional tapes would satisfy his definition of the self-duplicating entities, and copying errors would be identified as genetic mutations.

We now come to the question of the relation of von Neumann machines, and other similar devices, to living material. Perhaps it is important to note at the outset that any mechanism involving the transfer of information from one generation to the next can possess the basic feature of a self-instructive replicating entity. In fact, this feature has generated one of the most important difficulties facing man. When the first man scratched a piece of information on the wall of a cave, he invented a system that has its own genetics. Furthermore, the resulting evolution is directed and, as such, is far faster than the selection of random mutations, which has thus far characterized the biological evolution of man. As an example, one might cite the speed with which the memory capacity of computing machines has evolved in the past decade and a half. To achieve the same quantitative improvement by biological evolution would have required hundreds of millions of years. This dramatic difference in the rate of man's evolution compared to the evolution of the devices he invents poses a central issue of man's survival.

Although we are willing to place such devices as the von Neumann self-duplicating automata and living material in the class of self-instructive replicating agents, there is an important difference of origin. We entertain as plausible the hypothesis that the archetype of living objects originated from nonreplicating subunits by polymerization into chains capable of making copies of themselves by a mechanism that initially employed only their own chemical reactivities. We see today, at least dimly, how the same sort of reactions that generate new copies of DNA enzymatically could have taken place nonenzymatically by chemical reactions, which we understand reasonably well. Thus, we are willing to grant the spontaneous origin of living, self-instructive, replicating entities. It is difficult to see how the same sort of thing could occur with the tapes of the von Neumann automata. In other words, the basic difference is that, in the inanimate case, we are virtually forced to invoke an act of creation by some intelligent agent. The origin of living material demands no such postulate.

Precellular evolution

We now come to the central issue of our discussion, namely, the evolutionary events that preceded the appearance of cells. Basically, we assume that the first self-duplicating objects were genes, i.e., DNA or RNA replicating by means of the hydrogen-bond recognition device. These are the only cellular macromolecules we know that contain in their chemical structures the inherent potential of carrying through a copying process. A given polynucleotide strand can, in principle, serve as a catalytic surface to attract complementary activated nucleotides that would be automatically aligned in a complementary array on the surface of the strand, ready for subsequent polymerization. That this can happen without the aid of protein catalysts is indicated by recent experiments of Orgel and his collaborators (Sulston et al., 1969).

Cells, as we know them, can be looked upon as inventions of the nucleic acid genetic elements, made to provide a local environment optimally suitable for the production of more genetic material. The progress of cells to multicellular organisms can be interpreted as devices that permit DNA to occupy more and more terrestial space, culminating with the invention of man, who provided DNA with the opportunity to explore extraterrestial possibilities.

One of the most difficult evolutionary phases to examine is the period of precellular evolution. What were the rules of the game? In that period, the environment was looking not at gene products but at the genetic material itself in making decisions about which genetic variant was more suitable for survival.

An approach to such problems would be available if the nucleic acid replicating mechanism could be isolated so that the replication of genetic material could be studied in the test tube. If this could be achieved, in terms of extensive and continuous synthesis, one could begin to vary the environmental parameters in an attempt to uncover the kinds of selective forces that can be imposed directly on replicating genetic material.

In the biological universe, there are two types of organisms: one that uses DNA and another that uses RNA as genetic material. The RNA system was the first to yield an experimental situation in which evolutionary problems could be explored. The probable reason is that, although the general mechanism of replication of RNA is similar to that of DNA, it differs in certain important simplifying details.

The event that stimulated our group to institute an effort to study the RNA replicating system was the discovery by Loeb and Zinder (1961) of the RNA bacteriophage, f2. This was rapidly followed by the isolation of related phages such as MS2 (Strauss and Sinsheimer, 1963), R17 (Paranchych and Graham, 1962), and others. The armamentarium accumulated during several decades of T-phage technology thus became available to persons dealing with RNA viruses. Some of the difficulties and disadvantages inherent in the use of plant and animal systems could now be obviated, and a number of laboratories, including our own, quickly took advantage of the opportunities provided.

In what follows I describe briefly the key experiments that led to the successful isolation of the RNA replicating system, and summarize our efforts to study the extracellular evolution that it made possible.

The problems of communication between an RNA virus and its host cell

All organisms that use RNA as their genomes are mandatory intracellular parasites. Therefore, they must carry out a major portion of their life cycle in cells that use DNA as genetic material and RNA as genetic messages. On entry, the viral RNA is faced with a problem of inserting itself into the flow pattern of cellular information in order to communicate its own instructions to the synthesizing machinery. One method of so doing depends on whether an RNA virus employs the host DNA-to-RNA-to-protein pathway of information flow. This could take place either because the DNA of the host already contains a sequence homologous to the viral RNA (i.e., the escaped genetic message hypothesis) or because such DNA sequences are generated subsequent to infection by a reversal of transcription (i.e., of the RNA synthesizing reaction that is dependent on DNA). Both hypotheses predict that the DNA of infected cells should contain sequences complementary to viral RNA.

It is clear that a decision on the existence or nonexistence of homology between viral DNA and the infected host DNA is a necessary prelude to further experiments designed to delineate the molecular details of the life history of an RNA genome.

In an attempt to settle this issue, we (Doi and Spiegelman, 1962) employed the specific DNA-RNA hybridization test (Hall and Spiegelman, 1961) combined with the subsequently developed (Yankofsky and Spiegelman, 1962a) use of ribonuclease to eliminate nonspecific pairing. The sensitivity required had already been attained in the course of experiments that identified the DNA complements of ribosomal RNA (Yankofsky and Spiegelman, 1962a, 1962b) and of tRNA (Giacomoni and Spiegelman, 1962; Goodman and Rich, 1962). Under conditions in which the expected hybrid complexes were observed between 23S rRNA and DNA, none was detected between the RNA of the bacteriophage MS2 and the DNA derived from cells infected with this virus. The viral RNA used in these experiments was labeled with ³²P at a specific activity, which would have permitted hybrid detection even if the DNA had contained only one-tenth of an RNA equivalent per genome. This insured a meaningful interpretation of the negative answer.

The negative outcome of the hybridization test implied that the DNA-RNA pathway is not employed in the life cycle of the RNA phages. Further support for this view came from the experiments of Cooper and Zinder (1962), who showed that infection of a mutant that lacked thymine under conditions in which DNA synthesis was suppressed to the extent of 97 per cent resulted in undiminished yields of virus.

It must be recognized that, in a logically rigorous sense, all the evidence provided is negative and, as such, cannot be used to eliminate a proposed mechanism. Nevertheless, the absence of any evidence of DNA involvement was generally accepted to imply that RNA bacteriophages had evolved a DNA-independent mechanism of generating RNA copies from RNA. The next obvious step was to identify and then to isolate the new type of RNA-dependent RNA polymerase (replicase) predicted by this line of reasoning.

The search for RNA replicase and template specificity

The search for a replicase unique to cells infected with an RNA virus is complicated by the presence of a variety of enzymes which can incorporate the ribonucleotides either terminally or subterminally into pre-existent RNA chains. Further, there are others (e.g., transcriptase, RNA phosphorylase, polyadenylate synthetase) which can mediate extensive synthesis of polynucleotide chains. The complications introduced by these and other enzymes can be ameliorated by suitable adjustments of the assay conditions to minimize their activity. It was clear at the outset, however, that claims for a new type of RNA polymerase would ultimately have to be supported by evidence for RNA dependence and a demonstration that the enzyme possesses some unique characteristic that differentiates it from the known RNA polymerases.

In addition to these enzymological difficulties, we recognized another potential complication inherent in the fact that an RNA virus must always operate in a heterogenetic environment replete with strange RNA molecules. The point at issue may perhaps best be described in rather naive and admittedly anthropomorphic terms. Consider an RNA virus approaching a cell some 10⁶ times its size and into which the virus is going to inject its only strand of genetic information. This strand codes for the new kind of enzyme required for the replication of the viral genome. Even if the protein-coated ribosomal RNA molecules are ignored, the cell cytoplasm still contains thousands of RNA molecules of various sorts. If the new RNA replicase were indifferent and copied any RNA molecule it happened to meet, what chance would the original injected strand have of multiplying?

Admittedly, there are several ways out of this dilemma. One could, for example, segregate the new enzyme and the viral RNA in some corner in which the replication could be carried out undisturbed by the mass of the cellular RNA components. Because it had experimental consequences, however, we entertained the then-unusual hypothesis that the virus is ingenious enough to design a replicase which would recognize the genome of its origin and ignore all other RNA molecules.

Initially, we could not know which solution had been adopted by the virus to solve the dilemma we posed, or even if the dilemma were real. The possibility that it did exist, however, and that template selectivity by the replicase might be the chosen solution meant that the implications could not be ignored; if true, to disregard them would guarantee that the attempt to isolate the relevant enzyme would inevitably end in failure. In particular, this meant that, in the search for replicase, we could not afford the luxury of employing any RNA conveniently available in the usual biochemical laboratory. It demanded the use of the specific viral RNA as the challenging template at all stages of enzyme purification. Finally, this line of reasoning could be pushed to its ultimate pessimistic conclusion. It might be that fragments do not possess the proper recognition structures; in that case, a further demand would have to be imposed—the viral RNA employed in the assays during enzyme purification must be monitored for its size to insure intactness. This meant that assays in the presence of contaminating nucleases might be completely meaningless.

THE MS2 REPLICASE Despite all these potential obstacles, many of which were actually realized, our first success was achieved in 1963 with *E. coli* infected with the MS2 phage (Haruna et al., 1963). A procedure involving negative protamine fractionation combined with column chromatography yielded what resembled a relevant enzyme activity. Most important of all, the preparation exhibited a virtually complete dependence on added RNA for activity, permitting a test of the expectation of specific template requirements. The results of these tests are summarized in Table I. It will be seen that in the responses of the MS2 replicase to the various kinds of nucleic acids a striking preference for its own RNA was revealed. No significant response was observed with the tRNA or the rather similar RNA of the host cell. It would appear that our intuitive guess was confirmed. Producing a polymerase which ignores cellular RNA components guarantees that replication is focused on the single strand of the incoming viral RNA, the ultimate origin of progeny.

The announcement of the specific template requirement of the RNA replicase was greeted with what may best be

TABLE I

Template specificity of purified RNA-dependent polymerase

The standard reaction of 0.25 ml contained the following in μ M: Tris-HC1 pH 7.5, 21; MgCl₂, 1.4; MnCl₂, 1.0; KCl, 3.75; mercaptoethanol, 0.65; spermine, 2.5; phosphoenolpyruvate (PEA), 1.0; (NH4)2LO4, 70; CTP, ATP, GTP, and UTP, 0.5 each. In addition, it contained pyruvate kinase (PEA kinase), 5 µg; DNAase, 2.5 μ g and, where indicated, 10 μ g of the polynucleotide being tested as template. Enzyme was assayed at levels between 50 and 300 µg of protein per sample. DNAase was always omitted in assays for DNA-dependent polymerase activity. Incubations were carried out at 35° C for 10 minutes and terminated by placing the reaction mixture in an ice bath and by the addition of 0.15 ml of neutralized saturated pyrophosphate, 0.15 ml of neutralized orthophosphate, and 0.1 ml of 80 per cent of trichloracetic acid (TCA). The precipitate was washed onto a millipore filter and washed five times with 10 ml of cold 10 per cent TCA containing 0.9 per cent of Na pyrophosphate. The millipore membrane was then dried and counted in a liquid scintillation counter. The pyrophosphate is included in the wash to depress the zero time backgrounds to acceptable levels (40–70 cpm per sample containing input counts of 1 \times 106 cpm). (Haruna et al., 1963).

described as "well-controlled enthusiasm." It should be noted that, thus far, template specificity had not been observed in any of the known nucleic acid polymerases, including the Kornberg enzyme, the RNA phosphorylase, and the RNA polymerase that is dependent on DNA. It should be noted, however, that all these cellular enzymes were evolved in an essentially closed genetic system. These enzymes were rarely faced (except in virus infection) with the problem of deciding whether a particular nucleic acid was genetically related to it or not. In contrast, the RNAdependent RNA polymerases induced by RNA viruses *always* had to function in a heterogenetic environment and therefore evolved under conditions in which they were continually required to ask the question, "Do you belong to me?"

The fact that we could offer a plausible argument to explain why viral RNA replicases might possess the property of specific template requirements probably only served to increase skepticism. In addition, doubt was simultaneously introduced by August and his coworkers (August et al., 1963; August et al., 1965; Shapiro and August, 1965), who questioned the specificity of the replicase reaction. They prepared an enzyme from E. coli infected with the SU-11 mutant of the f2 bacteriophage. The preparation showed partial dependence on RNA, and appeared to respond to a variety of RNA molecules, including ribosomal RNA. As we pointed out (Spiegelman and Haruna, 1966a, 1966b), however, the very large amounts required for stimulation in their systems made it uncertain whether the RNA was functioning as a template or was serving as a scavenger to protect the product of an endogenous reaction from nuclease digestion.

It was not until 1967 (Fiers et al., 1967) that our isolation of the MS2 replicase was repeated and its specific template requirements were confirmed.

CONFIRMATION OF SPECIFIC TEMPLATE REQUIREMENTS WITH THE $Q\beta$ REPLICASE Template specificity was not accepted in 1963, and further evidence was clearly needed to support so novel a concept. Our line of reasoning predicted that replicases induced by other viruses would possess a similar preference for their homologous templates. It seemed desirable, therefore, to check this with another virus, preferably one unrelated to the MS2 group. The Q β phage of Watanabe (1964) was chosen because of its immunological and other chemical differences (Overby et al., 1966a, 1966b). In addition, it had the advantage of an excellent difference in the molar ratios of adenine (A) and uracil (U). As a result, one could readily distinguish the viral (plus) strand from its complement (minus) strand, a possibility not available with any of the RNA phages discovered previously. Finally, an unexpected windfall was the remarkable stability of the $Q\beta$ replicase, which made it much easier to

handle enzymologically than the replicases of the MS2 group.

The isolation and purification of the $Q\beta$ replicase followed, with slight modifications, the procedures worked out earlier for the MS2 replicase. The general properties of the $Q\beta$ replicase were similar to those observed in the MS2 replicase, including requirements for all four riboside triphosphates and magnesium. The ability of various RNA molecules to stimulate the $Q\beta$ replicase to synthetic activity at saturation concentrations of homologous RNA is recorded in Table II. The response of the $Q\beta$ replicase is in accord

TABLE II

Response of $Q\beta$ replicase to different templates

As in all cases, assay for DNA-dependent activity is carried out at 10 μ g of DNA per 0.25 ml of reaction mixture. Input levels of template Q β RNA were 1 μ g per 0.25 ml. Control reactions containing no template yielded an average of 30 cpm. Numbers represent counts per minute (cpm). (Haruna and Spiegelman, 1965a.)

 Qβ	4929
TYMV	146
MS2	35
Ribosomal RNA	45
sRNA	15
Bulk RNA from infected cells	146
Satellite virus	61
DNA (10 µg)	36

with what we have previously noted for the MS2 enzyme, the preference being clearly for its own template. The heterologous viral RNAs, MS2, and STNV are completely inactive, as are the ribosomal and transfer RNA species of the host cell. It is important to note that, as in the case of MS2 replicase, the absence of response in DNA shows that our purification procedure eliminates detectable evidence of active transcriptase from our enzyme preparations.

INTACTNESS REQUIREMENT AND THE "AMPHORA" MODEL OF TEMPLATE RECOGNITION An obvious device to explain the requirement for a specific template would invoke the recognition of a beginning sequence, a possibility open to the simple test of challenging the replicase with fragmented preparations of homologous RNA. If the initial sequence is the sole requirement, RNA fragmented to half and quarter pieces should serve as templates. One might perhaps expect that the initial synthetic rate with fragments would be the same as with intact templates, although the reaction might terminate sooner because release of the enzyme from the template might require the terminal sequence. A different response would, however, be predicted if a secondary structure requiring intact molecules were involved in the recognition mechanism. It was found (Haruna and Spiegelman, 1965a, 1965b) that randomly fragmented material is unable to stimulate the replicase to anywhere near its full activity. Half pieces achieve approximately 10 per cent of the rate of the intact strand, and the rate obtainable with quarter pieces is only 2 per cent of normal. Further, in both cases the reaction terminates quickly.

The replicase is unable to employ properly the fragments of its own genome as templates, which argues against a recognition mechanism in only the beginning sequence. The enzyme can apparently "sense" when it is confronted with an intact RNA molecule, which implies that some element of secondary structures is involved. A plausible, formal explanation can be proposed in terms of "functional circularity." A decision on the intactness of a polynucleotide chain can be made readily by an examination of both ends for the proper sequences. Such an examination would be physically aided by forming an "amphora"-like structure, using terminal sequences of overlapping complementarity. The enzyme could then recognize the resulting doublestandard region. This amphora model is offered only as an example of how an enzyme could simultaneously decide on both sequence and intactness. Whatever the details turn out to be, it appears that the RNA replicases are designed to minimize the futility of replicating either foreign sequences or incomplete copies of their own genome.

The nature of the product synthesized

PHYSICAL AND CHEMICAL PROPERTIES By 1965, the purification of $Q\beta$ replicase had been brought to a stage at which it was largely freed of contaminating nuclease. The enzyme was virtually dependent on added RNA and could mediate almost unlimited syntheses of RNA over long periods of time, as may be seen from Figure 1. It seemed desirable, therefore, to begin a study of the product produced in extensive synthesis. As can be seen in Figure 2, the synthetic material was indistinguishable in size from the RNA obtained from virus, and its base composition was also identical chemically. Naturally, we wanted more subtle information, and turned to our enzyme to provide it.

RECOGNITION OF PRODUCT BY THE REPLICASE The ability of replicase to distinguish one RNA molecule from another can be used to provide information pertinent to the question of the similarity between the original template and the synthesized product. Two sorts of readily performed experiments can show whether the product is recognized by the enzyme as a template. One approach is to examine the kinetics of RNA synthesis at template con-

FIGURE 1 Kinetics of replicase activity. Each 0.25 ml contained 40 μ g of protein and 1 μ g of Q β RNA. See Figure 3 for further details. The specific activity of the ³²UTP (uridinetriphosphate) was such that the incorporation of 4000 cpm corresponds to the synthesis of 1 μ g of RNA. (From Haruna and Spiegelman, 1965a.)

FIGURE 2 Sedimentation analysis of product of extensive syntheses by a purified replicase. A standard reaction mixture contained 50 μ g of "purified" enzyme protein and 0.2 μ g of Q β RNA. The reaction was continued for 40 min. at 35° C, during which a 30-fold synthesis had occurred. To 0.1 ml of the reaction mixture were added 0.01 ml of 20 per cent sodiumdodecylsulphate, 0.005 ml ³H-Q β RNA; 0.20 ml 0.01 M tris, pH 7.4; and 0.005 M MgCl₂. It was then layered onto a linear gradient of 2.5 per cent to 15 per cent sucrose in 0.01 M tris, pH 7.4; 0.005 M MgCl₂; 0.1 M NaCl, and centrifuged at 25,000 rpm for 12 hours at 10° C in the Spinco SW-25 rotor. (Pace and Spiegelman, 1966a.)

centrations that start below those required to saturate the enzyme. If the product can serve as a template, a period of autocatalytic increase of RNA should be observed. Exponential kinetics should continue as long as there are enzyme molecules unoccupied by template. However, when the product saturates the enzyme, the synthesis should become linear.

A second type of experiment is a direct test of the ability of the synthesized product to function as an initiating template. Here a synthesis of sufficient extent is carried out to insure that the initial input of RNA becomes a quantitatively minor component of the end product. The synthetic RNA can then be purified and examined for its template functioning capacities, a property readily examined by a saturation curve. If the response of the enzyme to variations in concentration of product is the same as that observed with authentic viral RNA, one would have to conclude that the product generated in the reaction is as effective a template for the replicase as is RNA obtained from the mature virus particle. We performed both types of experiments (Haruna and Spiegelman, 1965c). Figure 3 shows the

FIGURE 3 Template saturation of "replicase." In addition to $40 \mu g$ of enzyme protein, each standard reaction volume of 0.25 ml contained the following: 21 µM tris HCl, pH 7.4; 3.2 µM MgCl₂; 0.2 µM each of CTP, ATP, UTP, and GTP. The reaction is run for 20 min. at 35° C and terminated in an ice bath by the addition of 0.15 ml of neutralized saturated pyrophosphate, 0.15 ml of neutralized saturated orthophosphate, and 0.1 ml of 80 per cent trichloracetic acid. The precipitate is transferred to a membrane filter and washed 7 times with 5 ml of cold 10 per cent TCA. The membrane is then dried and counted in a liquid scintillation spectrometer. The washing procedure yields zero time values of 80 cpm with input counts of 1 x 106 cpm. The radioactively labeled ³²UTP was synthesized as detailed earlier (Figure 1) and was used at a level of 1 x 10⁶ cpm/0.2 μ M. The enzyme was isolated from E. coli (Q 13) infected with bacteriophage QB as detailed by Haruna and Spiegelman (1965c).

saturation curve we obtained with a fixed amount of enzyme and varying amounts of template input. It will be observed that saturation of the enzyme occurs at a level of 1 microgram of viral RNA per reaction mixture. Syntheses were then started at well below saturation levels; the results obtained are summarized in Figure 4. We note that autocatalytic synthesis takes place until the amount of RNA produced reaches the 1-microgram level, whereupon it becomes linear. The results are plotted both arithmetically and semilogarithmically to permit easier comparison.

Figure 5 compares the enzyme-saturation ability of RNA synthesized in the test tube with that of RNA obtained

FIGURE 4 The kinetics of RNA synthesis. A 2.5-ml reaction mixture was set up containing the components at the concentrations specified in the legend for Figure 1. The mixture contained 400 μ g of enzyme protein and 2 μ g of input Q β RNA, so that the starting ratio of template to enzyme was one-fifth of the saturating level. At the indicated times, 0.19-ml aliquots were removed and assayed for

radioactive RNA, as detailed in Figure 3. The ordinates for cpm and μ g of RNA synthesized refer to those found in 0.09-ml samples. The data are plotted against time arithmetically on the right, and semilogarithmically on the left. The arrows indicate change from autocatalytic to linear kinetics. (From Haruna and Spiegelman, 1965c.)

FIGURE 5 Saturation of enzyme by synthesized RNA compared to viral RNA. The experiment was carried out exactly as detailed in the legend for Figure 1. The circles refer to the values obtained with RNA isolated from virus particles; the triangles, to the rates obtained with the RNA synthesized in the experiment of Table II. Because, in the latter case, the template used was labeled with ³²P, ³H-UTP at 1 x 10⁶ cpm per 0.2 μ M was used to follow the synthesis. All preparations and counting of samples were carried out as described in Figure 3. (From Haruna and Spiegelman, 1965c.)

from mature virus particles. The synthesis in this case was 60-fold, so the initial RNA constituted less than 2 per cent of the material being added. It is clear from the results shown in Figure 5 that the response of the enzyme to increasing levels of synthetic RNA is identical with that observed in authentic viral RNA isolated from the Q β particles.

The data support the assertion that the reaction produces a polynucleotide of the same molecular weight (1×10^6) as viral RNA, and one the replicase cannot distinguish from its homologous genome. Evidently the enzyme in the test tube is, at the very least, faithfully copying the recognition sequences employed by the replicase to distinguish one RNA molecule from another.

EVIDENCE FOR THE SYNTHESIS OF AN INFECTIOUS VIRAL RNA The next question concerns the extent of the similarity between product and template. Have identical duplicates been produced? The most decisive test would determine whether the product contains all the information required to program the synthesis of complete virus particles in a suitable test system. The success recorded above encouraged us to attempt the next phase of the investigation, i.e., to subject the synthesized RNA to this more rigorous challenge (Spiegelman et al., 1965).

The ability to perform these experiments depended on the fact that one could introduce viral nucleic acid into protoplasts of bacteria, i.e., bacterial cells from which the cell wall had been removed. Once inside the cells, the RNA is translated and replicated to form complete virus particles which can be assayed by the usual plaque assay on intact cells.

As a first approach, the appearance of newly synthesized RNA was compared with the number of infectious RNA strands during the course of an extensive synthesis. We took aliquots from a reaction mixture to determine the amount of radioactive RNA that was synthesized, and purified the phenol for the infectivity assay. As is illustrated in Figure 6, increase in RNA is paralleled by a rise in the number of infectious units.

This kind of experiment offers plausible evidence for the infectivity of newly synthesized and radioactively labeled RNA. It is not, however, conclusive, because there is still a possibility that the agreement is fortuitous. It must be recalled that the infective efficiency of RNA strands is low of the order of 1 in 10⁶. One could therefore argue, however implausibly, that the enzyme is activating the input RNA to higher levels of infective efficiency while it is synthesizing new, noninfectious RNA. The concordance of the rather complex combination of exponential and linear kinetics of the two processes would then be just an unlucky coincidence.

To answer issues raised by such arguments, one must

design experiments to eliminate the possibility that the input RNA is involved in the infectivity tests. There are several possible approaches to this problem, including the use of heavy isotopes and the separation of newly formed strands by density difference. One can, however, perform a much simpler experiment by taking advantage of the fact that we are dealing with a presumed self-propagating entity.

Consider a series of tubes, each containing 0.25 milliliter of the standard reaction mixture, but with no added template. The first tube is inoculated with 0.2 microgram of $Q\beta$ RNA and incubated long enough to synthesize 10 times as much radioactive RNA. A one-tenth aliquot is transferred to the second tube, which is permitted to synthesize about the same amount of RNA, a portion of which is transferred to a third tube, and so on. If each successive synthesis produces RNA that can serve to initiate the next one, the experiment can be continued indefinitely and, in

FIGURE 6 Kinetics of RNA synthesis and formation of infectious units. An 8-ml reaction mixture was set up, and samples were taken as follows: one ml at 0 time and 30 min.; 0.5 ml at 60 min.; 0.3 ml at 90 min.; and 0.2 ml at all subsequent times. Twenty λ were removed for assay of incorporated radioactivity. The RNA was purified from the remainder, radioactivity being determined on the final product to monitor recovery. (From Spiegelman et al., 1965.)

particular, until the point is reached at which the initial RNA of tube one has been diluted to an insignificant level. If in all the tubes, including the last one, the number of infectious units corresponds to the amount of radioactive RNA found, convincing evidence is offered that the newly synthesized RNA is indeed infectious.

A complete account of such a serial transfer experiment

unit ascribable to the initiating RNA, and the fifteenth tube contained less than one strand of the initial input. Nevertheless, every tube, including the last, showed an increment in infectious units corresponding to the amount of radioactive RNA found. In other words, the newly synthesized RNA was as infectious as the material obtained originally from the virus particle.

FIGURE 7 RNA synthesis and formation of infectious units in a serial transfer experiment. Sixteen reaction mixtures of 0.25 ml were set up, each containing 40 γ of protein and the other components specified for the "standard" assay. 0.2 γ of template RNA was added to tubes 0 and 1; RNA was extracted from the former immediately, and the latter was allowed to incubate for 40 minutes. Then 50 λ of tube 1 was transferred to tube 3, and so on, each step after the first involving a 1 to 6 dilution of the input material. Every tube was transferred from an ice bath to the 35° C water bath a few minutes before use to permit temperature equilibra-

to determine the amount of ³⁵P-RNA synthesized, and the product was purified from the remainder. Control tubes incubated for 60 minutes without the addition of the 0.2 γ of RNA showed no detectable RNA synthesis, nor any increase in the number of infectious units. All recorded numbers are normalized to 0.25 ml. The ordinates represent cumulative increases of infectious units and radioactive RNA in each transfer; the abscissae record elapsed time and the transfer number. Further details are to be found in Spiegelman et al. (1965).

can be found in Spiegelman et al. (1965), and Figure 7 describes the outcome. We knew the molecular weight and the amount of RNA put into the initial tube, so we could readily calculate how many tubes should be used to insure that the last tube contained less than one strand of the initial input. In this experiment, aside from the controls, 15 transfers were made, each resulting in a dilution of one to six. By the eighth tube there was less than one infectious

A rigorous proof that the added RNA is the self-duplicating entity

The central issue I now consider is one I have already noted in my introductory remarks. It stems from the fact that two informed components are present in the reaction mixture replicase and RNA template. None of the experiments thus far described *proved* that the RNA synthesized in this system is a self-duplicating entity. As we have seen, what is required in such situations is a rigorous demonstration that the RNA, not the replicase, is the instructive agent in the replicative process.

A definitive decision would be provided by an experimental answer to the following question: If the replicase is provided alternatively with two distinguishable RNA molecules, is the product always identical to the initiating template? A positive outcome would establish that the RNA is directing its own synthesis and simultaneously eliminate any remaining possibility that the RNA present as a contaminant of the enzyme preparation is activated. Experiments to settle these issues were undertaken by Pace and Spiegelman (1966a, 1966b).

The discriminating selectivity of the replicase for its own genome as a template makes it impossible to employ any kind of heterologous RNA in the test experiments, and we took recourse in mutants. For ease in isolation and simplicity in distinguishing between mutant and wild phenotype, temperature-sensitive (ts) mutants were chosen. The ts mutant grows poorly at 41° C as compared with 34° C. The wild type grows equally well at both temperatures.

We should be able to determine whether the product produced by a normal replicase primed with ts-Q β RNA is mutant or wild type. As in previous investigations, this is done best by a serial transfer experiment, to avoid the ambiguity of examining reactions containing significant quantities of initiating RNA. The basic experiment is as follows: The mutant virus is grown at the permissible temperature and the RNA is extracted. This RNA is then presented to a wild-type enzyme, and the virus particles produced from the newly synthesized RNA in bacterial protoplasts are examined. If they retain the temperaturesensitive phenotype, it is clear that the RNA is wild type, it is the enzyme that is geared to synthesize RNA, and the initiating template simply serves as a stimulator of synthesis.

Accordingly, we prepared seven standard reaction mixtures, each containing 60 micrograms of $Q\beta$ replicase, isolated from cells infected with normal virus. To the first reaction mixture we added 0.2 microgram of tsRNA and allowed synthesis to proceed at 35° C. After a suitable interval, we used one-tenth of this reaction mixture to initiate a second reaction, which, in turn, was diluted into a third, and so on for seven transfers. A control series was carried in a manner identical to that just described, except that we added no RNA to the first tube. We examined aliquots from each reaction for radioactivity in the material that was precipitated by trichloracetic acid and also assayed for infectious RNA at 34° and 41° C. Figure 8 summarizes the outcome of the experiment in a cumulative plot of the RNA synthesized and the plaque formers detected at the two test temperatures. It is clear that the RNA synthesized

has the ts phenotype. Although the plaque formation tested at 34° C increases in parallel with the new RNA that is synthesized, no such increase takes place when the tests are carried out at 41° C. It should be noticed (on the upper panel of Figure 8) that no significant synthesis of either RNA or infectious units was observed in the control series of tubes that lacked initiating templates.

Extracellular Darwinian experiments with the replicating RNA molecules

The experiments just described demonstrated a specific response of one and the same enzyme preparation to the particular template added. This proved that the RNA is the instructive agent in the replicative process and hence

FIGURE 8 Synthesis of mutant RNA. Each 0.25-ml reaction contained 60 μ g of Q β replicase purified through CsCl and sucrose centrifugation. The first reaction was initiated by addition of 0.2 μ g of tsRNA. Each reaction was carried out at 35° C for 25 min., whereupon 0.02 ml was withdrawn for counting and 0.025 ml was used to prime the next reaction. All samples were stored frozen at -70° C until infectivity assays were carried out at 41° C and 34° C. A control series was carried out in which no initiating RNA was added. (From Pace and Spiegelman, 1966b.)

satisfies the operational definition of a self-duplicating entity. An opportunity is thus provided for studying the evolution of a self-replicating nucleic acid molecule outside a living cell. It should be noted that this situation mimics an early, precellular evolutionary event, when the environmental selection presumably operated directly on the genetic material, rather than on the gene product. The comparative simplicity of the system and the accessibility of its known chemical components to manipulation permit the imposition of a variety of selection pressures during growth of replicating molecules. As we noted earlier, this experimental situation should permit us to explore at least some of the rules of the game that must have been played in the evolution of living material before the advent of cells.

In the universe provided to them in the test tube, the RNA molecules are liberated from many of the restrictions derived from the requirements of the complete viral life cycle. The only restraint imposed is that they retain whatever sequences are involved in the recognition mechanism employed by the replicase. Thus, sequences which code for the coat protein, replicase, and attachment protein components may now be dispensable. Under these circumstances, it is of no little interest to design an experiment which attempts an answer to the following question: What will happen to the RNA molecules if the only demand made on them is the biblical injunction, "Multiply," with the biological proviso that they do so as rapidly as possible? The conditions required are readily obtained by a serial transfer experiment in which the intervals of synthesis between transfers are adjusted to select the earliest molecules completed. If the sequences coding for the three viral proteins are unnecessary for the replicative act, these sequences become so much excess genetic baggage. Because the longer a chain is, the longer it takes to complete, molecules would gain an advantage by discarding any unneeded genetic information to achieve a smaller size and therefore a more rapid completion.

Isolation of Fast-Growing Variant (V-1) Mills et al. (1967) performed a series of 75 transfers (Figure 9), during which each reaction mixture was diluted 12.5 times in the next tube. The incubation intervals were reduced periodically as faster and faster growth was achieved. As can be seen from the insert in Figure 9, although RNA continued to be synthesized, the formation of infectious RNA ceased after the fourth transfer. A dramatic increase in the rate of RNA synthesis occurred after the eighth transfer.

It should be noted that this sort of evolutionary experiment has its own built-in paleology, for each tube can be frozen and its contents expanded whenever one decides to examine what happened at that particular period in the evolutionary process. We illustrate this by analyzing the products of several of the transfers in a sucrose gradient. The product of the first reaction (Figure 10) shows the 28S

FIGURE 9 Serial transfer experiment. Each 0.25-ml standard reaction mixture contained 40 μ g of Q β replicase and (³²P) UTP. The first reaction (0 transfer) was initiated by the addition of 0.2 μ g ts-1 (temperature-sensitive RNA) and incubated at 35° C for 20 min., whereupon 0.02 ml was drawn for counting and 0.02 ml was used to prime the second reaction (first transfer), and so on. After the first 13 reactions, the incubation periods were reduced to 15 min. (transfers 14–29). Transfers 30–38 were incubated for 10 min. Transfers 39–52 were incubated for 7 min., and transfers 53–74 were incubated for 5 min. The arrows above certain transfers (0, 8, 14, 29, 37, 53, and 73) indicate where 0.001–0.1 ml of product was removed and used to prime reactions for sedimentation analysis on sucrose. The inset examines both infectious and total RNA. The results show that biologically competent RNA ceases to appear after the fourth transfer. (From Mills et al., 1967.)

FIGURE 10 Sedimentation analysis of first transfer reaction. 0.002 ml of the 0 reaction was used to initiate a reaction for a first transfer reaction product. After completion, this reaction was adjusted to 0.2 per cent SDS, an aliquot was withdrawn, diluted to 0.2 ml in TE (tris-EDTA) buffer (0.01 m tris, pH 7.4, 0.003 m EDTA), and then layered onto a 5-ml linear sucrose (2-20 per cent in 0.1 m tris, pH 7.4, and 0.003 m EDTA). ³H-labeled bulk RNA of *E. coli* was included as internal size markers. (From Mills et al., 1967.)

peak characteristic of mature Q β RNA, as well as the peaks corresponding to the usual replicative complexes observed during in vitro synthesis (Mills et al., 1966). Products of subsequent transfers showed a gradual shift in the RNA to smaller S values. By the thirtieth transfer no molecules larger than 16S were found. By the fifty-fourth transfer, a single peak was found at about 15S, and, by the seventyfifth transfer, this peak had moved to a value of 12S (Figure 11). This single peak is due to the poor resolving

FIGURE 11 Sedimentation analysis of the 54th and 75th transfers. Details as in Figure 10. (From Mills et al., 1967.)

power of sucrose gradients and is composed of several components, as is easily shown by analysis on acrylamide gels, in which the replicative intermediates are readily resolved from the single-stranded forms. We determined the size of the variant by using acrylamide gel electrophoresis with internal markers. The position of the variant found in the seventy-fourth transfer (V-1) indicates that it has a molecular weight of 1.7×10^5 daltons, corresponding to

550 nucleotides. This means that, in response to the selection pressure for fast growth, the replicating molecule discarded 83 per cent of its genetic information.

The principal purpose of the experiment was to illustrate the potentialities of the replicase system for our examining the extracellular evolution of a self-replicating nucleic acid molecule. The seven samples we examined indicate that progress to a smaller size occurs in a series of steps.

Eighty-three per cent of the original molecule has been discarded, which means that neither the specific recognition nor the replicating mechanism requires the entire original sequence. In this connection, it should be noted that these variants, although abbreviated, are not equivalent to random fragments, because, as we have already seen, the latter are unable to complete the replicative act.

The availability of a molecule that has eliminated large and unnecessary segments provides an object with obvious experimental advantages for the analysis of many aspects of the replicative process. Finally, these abbreviated RNA molecules have a high affinity for the replicase but are no longer able to direct the synthesis of virus particles. This opens up a pathway toward a highly specific device for interfering with viral replication.

Cloning of Self-replicating Molecules In principle, the $Q\beta$ replicase system should be capable of generating clones descended from individual strands. The resulting clones would provide the sort of uniformity required for sequence and genetic studies. We (Levisohn and Spiegelman, 1968) succeeded in demonstrating that this can be attained.

As a first step, we isolated a new mutant, characterized by an ability to initiate synthesis at a low level of input. This was clearly necessary for our attempt at cloning. The selection of this type of mutant was accomplished by modifying the earlier, serial-selection procedures described in Figure 7. As shown in this Figure, the time intervals between transfers were decreased, but the dilution remained constant. In the experiments to be described, the time was kept constant and the dilution was increased as the transfers were continued. During a serial transfer experiment, the incubation interval was held constant at 15 minutes, and increasing selection pressure was achieved by recurrent sharp decreases in the dilution experienced by successive transfers from 1.25×10^{-1} to 2.5×10^{-10} .

The variant RNA that evolved by the seventeenth transfer was selected for further studies and was called Variant 2 (V-2). Figure 12 compares the response of the two variants, V-1 and V-2, to low-level inputs of template RNA in a 15minute incubation at 30 degrees. V-2 is clearly superior in growth at levels below 100 $\mu\mu\mu$ g of RNA. In fact, V-2 can initiate synthesis with 0.29 $\mu\mu\mu$ g of RNA which corresponds to the weight of one strand. A kinetic analysis reveals that, during the exponential growth phase, V-2 has a doubling time of 0.403 minute as compared with 0.456 minute for V-1. In a 15-minute period of logarithmic growth, V-2 can experience more doublings (i.e., a 16-fold increase) than can V-1. V-1 and V-2 have a similar electrophoretic mobility on polyacrylamide gels and the same base composition. They do, however, differ in sequence, as determined by oligonucleotide fingerprint patterns.

We obtained clones of RNA molecules in vitro by using an approach that depends on a straightforward comparison of the observed frequency distribution in a series of replicate syntheses with the frequency expected from the Poisson distribution. If one strand is sufficient to initiate synthesis, the proportion of tubes showing no synthesis should correspond to e^{-m} , m being the average number of strands per tube. Further, if the onset and syntheses are adequately synchronized, one should be able to identify tubes that received initially one, two, or three strands. These tubes should appear with frequencies corresponding to me^{-m}, (m²/2!)e^{-m} and (m³/3!)e^{-m}, respectively.

A reaction mixture containing 0.29 $\mu\mu\mu$ g of V-2 RNA per 0.1 milliliter was distributed at 0° C in 0.1-milliliter portions into each of 82 tubes. The tubes were placed

FIGURE 12 Comparison between the synthesis of Variant-1 (V-1) RNA and V-2 RNA when used as templates at very low concentrations. The indicated concentrations of V-1 RNA and V-2 RNA were added as templates to 0.125 ml of standard reaction mixture. After a 15-min. incubation at 38° C, the 32 P-UTP incorporated into acid-insoluble material was determined. (From Levisohn and Spiegelman, 1968.)

simultaneously in a bath of 38° C. and, after a 30-minute interval, the reactions were stopped simultaneously. If the assumption underlying the Poisson distribution has been satisfied by the conditions of the experiment, 36.8 per cent of the 82 tubes, that is to say 30.2, should show no synthesis. This is in excellent agreement with the 30 tubes found in Table III.

TABLE III

Distribution of template strands at an average input of one template strand per tube

A reaction mixture in which 13.2 μ g Variant-2 RNA were synthesized was diluted to a final concentration of 2.9 $\mu\mu\mu\mu$ /ml RNA into standard reaction mixture containing 7.8 \times 10⁵ cpm ³²P-GTP per 0.25 ml. Quantities of 0.1 ml were distributed into each of 82 tubes. After incubation of 30 minutes at 38° C, the acid-insoluble ³²P-GTP was determined. The average is for the actual number of counts after subtraction of the average of nine control tubes (22 cpm) to which no variant RNA was added. In this experiment 3240 cpm is equivalent to 1 μ g of variant RNA. (Levisohn and Spiegelman, 1968.)

Strands per Tube	P(r)	Among 8 Expected	2 tubes Found	
0	0.368	30.2	30	
1	0.368	30.2	29	
2	0.184	15.1	19	
3	0.0613	5.4	3	
4	0.0153	1.3	1	
2 3 4	0.184 0.0613 0.0153	15.1 5.4 1.3	19 3 1	

To identify tubes inoculated with one, two, three, or more strands, the sum of the counts observed in all tubes was divided by the number of template strands. The result, 309 counts per minute, is the average amount ascribable to a single template strand. The actual incorporation observed in each tube was divided by 309, and the result was rounded out to the nearest integer to yield an approximation of the number of strands that initiated synthesis in that tube. Table III shows a good agreement between the results expected from the Poisson distribution and those actually found. It is highly probable that a tube exhibiting an incorporation close to 309 cpm was, in fact, initiated by a single strand.

An interesting outcome of the last experiment is that 0.29 $\mu\mu\mu$ g indeed satisfied the Poisson expectation for an average of one strand of RNA. This permits an independent estimation of molecular weight as 174,000 daltons for V-2 RNA, in good agreement with the value deduced from gel electrophoresis.

The ability to clone variant RNA molecules in vitro has already proved useful for sequence analysis of V-2 (Bishop et al., 1968). The molecules also provide a necessary prerequisite for a genetic analysis.

Diverse variants isolated under different selective conditions

The experiments thus far described were concerned with the isolation of mutants possessing increased growth rates under standard conditions. We now turn our attention to a question of no little theoretical and practical interest and inquire whether other mutant types can be isolated. In effect, we are asking the following question: can qualitatively distinguishable phenotypes be exhibited by a nucleic acid molecule under conditions in which its information is replicated but never translated? We (Levisohn and Spiegelman, 1969) undertook to answer this question and, as will be seen, our results show that numerous distinguishable variants can be isolated, the number depending on the ingenuity expended in designing the appropriate selective conditions.

SELECTION OF "NUTRITIONAL MUTANTS" One general approach for obtaining a variety of mutants is to run the syntheses under less-than-optimal conditions with respect to a component or parameter of the reaction. If a variant arises that can cope with the imposed suboptimal condition, continued transfers should lead to its selection over the wild type. This can be done with variations in the level of the ribonucleoside triphosphates. It can be seen in Figure 13 that the rate of synthesis of V-2 begins to decrease sharply as the level of cytidine triphosphate (CTP) drops below 20

FIGURE 13 CTP concentration curve. Reaction mixtures of 0.125 ml containing the indicated concentrations of CTP and otherwise identical to "standard reaction mixture" were incubated for 30 min. at 38° C with 20 μ g Q β replicase and 0.01 μ g V-2 RNA. Subsequently, the acid-insoluble radioactivity was determined. In the "complete medium" (containing 100m μ M CTP) 1.6 μ g of V-2 RNA were synthesized. (From Levisohn and Spiegelman, 1969.)

millimicromoles per 0.125 milliliter. At a CTP concentration of 2 millimicromoles, the rate of synthesis of V-2 is only 25 per cent of normal. At 1 millimicromole of CTP, the rate decreases to 5 per cent of normal. With such information available, a search was made for variants that could replicate better than V-2 on limiting levels of CTP. A serial transfer experiment at 2 millimicromoles of CTP per reaction was initiated, with Q β RNA culminating after 10 transfers in the appearance of V-4. A second series of transfers at 1 millimicromole of CTP per reaction was then started with V-4 and after 40 transfers led to the isolation of V-6.

Variants V-4 and V-6 replicate 28 per cent and 56 per cent better, respectively, than does V-2 at low levels of CTP. This increased capacity might be explained on the basis of smaller sizes or modification of base composition toward a lower cytosine content. On polyacrylamide gel V-2 and V-6 showed no significant difference in chain length. Furthermore, as can be seen in Table IV, there is no significant difference in base composition.

TABLE IV

Base ratios of variants

The base composition of purified plus strands of Variant-2 and Variant-6. The numbers represent mole per cent. (Levisohn and Spiegelman, 1969.)

 Base	V-2	V-6	
 С	24.8	24.8	
Α	23.2	23.5	
G	26.6	26.7	
U	25.4	25.1	

Evidently the modifications leading to the properties possessed by variants 4 and 6 do not involve massive modifications in the composition of the molecule. The identification of the changes will require more subtle examination by nucleotide fingerprint patterns, and these are being carried out.

The most obvious pathways for solving the problem of low CTP were not employed, which leads one to consider more sophisticated devices for achieving the desired end result. It is useful here to recall that the mutant RNA molecules must form a complex with replicase, so changes in sequence that would leave such gross features as base composition and size unmodified could, nevertheless, lead to different secondary structures of the mutant molecules. These, in turn, could have allosteric effects on the replicase, permitting the complex to employ CTP more effectively at suboptimal concentrations. If such were the case, and there were a common site for the four riboside triphosphates as there is in DNA polymerase, as shown by Atkinson et al. (1969), it might be expected that a mutant selected for better replication on low CTP would also exhibit increased capacities to accommodate to low levels of the other riboside triphosphates. Table V summarizes data comparing

ATP concentration. Variant 6 was chosen to start a series of transfers in the reaction mixture that contained 1.5 millimicromoles of ATP, which led to the isolation of variant 8. The doubling time of variant 8 in the reaction mixture with

Limiting		Variant	Doubling Time Min.	Relative Slope	
Nucleotides	mµmoles			Compared with V-2	Compared with V-4
None	100	2	0.42	1.00	
		4	0.42	1.00	1.00
		6	0.35	1.21	1.21

TABLE V Logarithmic synthesis of variant RNA on limiting media

the logarithmic synthesis of variants V-4 and V-6 with that of V-2 on limiting levels of each of the four riboside triphosphates. The data show that the two variants selected on low CTP also do much better on limiting concentrations of the other three substrates. More definitive delineation of the underlying mechanism will require studies of substrates that bind with enzyme-complex and mutant and wild-type templates.

Selection of a Variant Resistant to an Inhibitory ANALOGUE Tubercidin is an analogue of adenosine in which the nitrogen atom in position 7 is replaced by a carbon atom. Tubercidin triphosphate (TuTP) inhibits the synthesis of $Q\beta$ RNA in vitro. However, TuTP cannot completely replace adenosine triphosphate in the reaction, although it can be incorporated into the growing chains. It was of some interest to see whether one could derive a mutant that would show resistance to the presence of this agent. In such experiments, it was desirable to have the ratio of the analogue to ATP as high as possible. To attain this more readily, we isolated a new variant by limiting the

1.5 millimicromoles of ATP was 2.8 minutes as compared with 8.4 minutes for V-6, the starting variant.

The replication rate of V-8 in a reaction mixture that contained 5 millimicromoles of ATP was inhibited fourfold with the additon of 30 millimicromoles of TuTP. A serial transfer was initiated with V-8 in the inhibitory medium and led to the isolation of V-9. The doubling time of V-9 in the presence of TuTP was 2.0 minutes as compared with 4.1 minutes for V-8. In the absence of TuTP, both variants synthesized with a 1.0-minute doubling time. It is clear that V-9 exhibits a specifically increased resistance to the inhibitory effect of TuTP. The resistance mechanism does not involve a more effective exclusion of TuTP. At 30 millimicromoles of TuTP and 5 millimicromoles of ATP, the ratio of U to A in the product was 3.6 for V-8 and 3.5 for V-9, the resistant mutant.

Table VI lists the variants isolated in the experiments described and summarizes the relevant information on their origins and conditions of selection. It will be noted that V-4 is an independent derivative from the parental QBRNA. Another variant, V-3 (not listed), was isolated

TABLE VI

Conditions used in isolation of variants

Variants were selected on standard reaction mixture, or on a standard reaction mixture modified to contain one of the four nucleoside-triphosphates at the indicated concentration. Starting with the RNAs indicated in column 3, a series of transfers were made with reaction product, diluted 1.25×10^4 . Subsequently, the dilution factor between transfers was gradually increased to about 1×10^{11} . (Levisohn and Spiegelman, 1969.)

Variant	Selective Limitations	RNA Used to Start Selection	No. of Transfers at Dilution of 1.25 \times 10 ⁴	Total No. of Transfers
V-2 ⁽⁶⁾	None	Qβ	0	17
V-4	2 mµmoles CTP	Qβ	5	10
V-6	1 mµmoles CTP	V-4	30	40
V- 8	1.5 mµmoles ATP	V-6	11	16
V- 9	5 m μ moles ATP +30 m μ moles TuTP	V-8	15	19

with limiting CPT, starting with V-2 instead of $Q\beta$ RNA. V-3 possesses phenotypic properties indistinguishable from those of V-4; thus one can arrive at the V-4 phenotype either from $Q\beta$ RNA or from V-2. It seems probable that $Q\beta$ RNA passes through the V-2 stage before arriving at the V-4 phenotype.

It will be of no little interest to compare the actual sequence changes among the mutants that differ in their relatedness and phenotypic properties. With this information available, one can begin to construct the probable modifications of the secondary structure. Only then will we be in a position to begin the attempt to understand the molecular basis of these new phenotypes.

Some theoretical and practical implications of extracellular Darwinian experiments

We pointed out previously that extracellular Darwinian selections may mimic that aspect of precellular evolution when environmental selection operated only on the replicating gene and not on the gene product. Such experiments provide some insight into the rules of these early stages of evolution. It was not obvious a priori what kinds of selective forces could be operative, as much depended on how many different ways a molecule could be selected by the environment as superior. The experiments reported here reveal an unexpected wealth of phenotypic differences that a replicating nucleic acid molecule can exhibit. It is true that many of these involve interactions between nucleic acid molecules and a highly evolved protein catalyst. It is possible, however, to imagine similar types of interactions with a primitive surface catalyst. Sequence changes which would increase the catalytic capacity slightly could have powerful selective effects in these precellular stages of evolving genetic material.

It should not escape the attention of the reader that this

phenomenon provides a possible solution to the following puzzling question: What pressures could have forced replicating nucleic acids toward greater complexity before they invented cells or subcellular components to help them replicate?

It is apparent, from the limited number of examples described, that a host of new mutant types possessing predetermined phenotypes can be isolated by varying other parameters of the system. In addition, one can expand the possibilities by introducing neutral agents (for example, proteins) with which the replicating molecules may interact. Selection can then be exerted to favor variants that can induce these foreign agents to become participants in the replicative process. Indeed, one might be able to persuade the RNA molecules themselves to acquire a weak catalytic function that would aid their replication.

Finally, I wish to note a practical implication of the mutant that is resistant to the inhibitory analogue, TuTP. These abbreviated variants possess various features that make them potentially powerful chemotherapeutic agents. They combine a high affinity for the replicase and a rapid growth rate. They compete effectively with a normal, viral nucleic acid for the replicase and thus halt the progress of virus production. To these properties we can now add a third—resistance to a chemotherapeutic agent that is effective against the original virus particle. All these features can be built into one variant by the kinds of serial selection described here, adding another dimension to the potential use of these agents as chemotherapeutic devices and opening up a novel pathway for the specific control of viral diseases.

83 Repressors and Genetic Control

WALTER GILBERT

How ARE GENES controlled? The Jacob and Monod (1961) model of genetic control proposed that control genes would make repressors which would turn off other genes. At the last Boulder meeting, Gunther Stent (1967) described this picture of control that had emerged from genetic studies in bacteria and bacterial viruses. However, since then our knowledge about the control of gene function has been given an explicit biochemical base through the isolation of several repressors (Gilbert and Müller-Hill, 1966; Ptashne, 1967; Riggs and Bourgeois, 1968; Pirrotta and Ptashne, 1969).

The particular model for genetic control put forward by Jacob and Monod contains two germinal ideas. One of these is the concept of separate, specific genes involved in the control of other genes-regulatory genes as distinct from "structural" genes. According to the model, these regulatory genes made substances that would directly affect some rate-determining step in the synthesis of the products of other genes. This rate-determining step defines a target for the control. Such a target, named an "operator," could be, for example, a specific point on a DNA molecule. The binding of a substance to the region of the DNA molecule that serves as an initiation point for the synthesis of messenger RNA clearly could block (or affect or enhance) the synthesis of that messenger. Alternatively, the target for control could be a region on a messenger RNA molecule. The binding of a control substance to such a messenger could easily be imagined to block the attachment of ribosomes and hence the synthesis of proteins. (I have used the term "bind" to supply a specific physical picture. As far as genetic arguments are concerned, any biochemical process that leads to the same result would serve. The control substance could modify bases, achieving the same ends through a chemical alteration of structure.)

The other idea is that the controlling substance itself will act as an intermediate to make a connection (a physical connection) between a small molecule—a compound acting as a signal—and the target for the control. A biochemical realization would be that the molecule serving as a signal could bind to the control substance to alter the affinity of the control substance for the operator. This proposal is a complete shift away from instructive theories of control, which require that there be a way in which the signal is like the act controlled: the enzyme to be called forth by the substrate (even formed upon the substrate in the primitive form of such theories), the antibody shaped by the antigen, or the sperm to contain a homunculus. The interposition between signal and act of a controlling substance, which interacts separately with a small molecule and the operator, permits the relationship of the small molecule to the enzyme called forth to be dictated only by evolutionary accident; there is no necessary structural relationship.

The explicit mechanism that Jacob and Monod suggested, that the control should involve a gene product that represses gene function, is an accident of the systems that were analyzed originally. It is true for phage lambda, for the enzymes of lactose utilization, for galactose, for glycerol, for the tryptophan biosynthetic enzymes, and for others, that the controlling gene makes a gene product that behaves as a repressor. (This has an explicit genetic meaning: in the absence of the control gene—if the gene is deleted, for example—the structural genes run at full rate. In a genetic complementation experiment, a cytoplasmic product of the control gene turns off the structural genes. General reviews of the various systems are by Epstein and Beckwith, 1968, and Dove, 1968.)

There are a number of other cases, however-genes N and Q of phage lambda that turn on the early and late functions of that phage, and the enzymes for the metabolism of arabinose and maltose, in which the structural genes will not function without the product of the control gene. These are examples of positive control, the regulatory gene product being necessary for expression. How such genes act is unknown. If such control is exerted at the DNA level, a positive control gene might make a factor (like the sigma factor, Burgess et al., 1969) that binds to the RNA polymerase and permits that enzyme to initiate on a new region of DNA, or to make a factor that binds to DNA, to open it for reading, or to act negatively to prevent a stopping of the reading of DNA by interfering with an RNA stop signal. Alternatively, a variety of steps at the RNA-to-protein level could be affected. It is still possible, however, that these positive control genes may act in a more trivial way by generating or shaping a small molecule that acts to interfere with a repressor made by some still-unidentified gene.

If the cell is to respond to a chemical signal coming from outside, a number of steps will intervene before that signal affects the synthesis of proteins. The chemical signal must penetrate, be concentrated, possibly altered, possibly trigger the release of other chemicals, which, in turn, serve as signals—each step requiring a specific enzyme or function, and so requiring the product of a specific gene. Genetically, each of these genes can be altered by mutation; each such mutation can appear as a "control" or "regulatory" effect. Exhaustive genetic analysis can only suggest which control genes affect the transmission of the signal and which specify the actual way in which the process is controlled. Only biochemical analysis can ultimately prove the mechanism. Now that several repressors have been isolated, we can understand their functioning in detail.

The lactose operon

One of the genetic systems that has been exploited most successfully involves the genes for the enzymes of lactose metabolism in *E. coli*. Figure 1 shows a schematic genetic map of this region of the *E. coli* chromosome. There are three structural genes: z, the gene for β -galactosidase, the enzyme that splits lactose into glucose and galactose; y, the gene producing a protein that is involved in the permeation (and active concentration) of lactose; and a, the gene for the thiogalactoside transacetylase, an enzyme that has no known function in vivo, strains deleted for the a gene behaving normally in all tests. These three contiguous genes are controlled together, the levels of the three products changing in a coordinate fashion. Such a set of genes is called an operon, and is thought of as being under the control of an operator.

Three controlling elements are shown on the map: the *i* gene; *p*, the promoter; and *o*, the operator. The *i* gene makes a controlling substance, a repressor. We know this through the variety of mutations that exist in this gene. The basic defining mutation is the change to i^- : when no product is made by the *i* gene—if it were deleted, for example —the structural genes function at full rate at all times; in the wild-type (*i*⁺) cell (in the absence of sugar), the enzymes are made only one-thousandth of the full rate. The crucial experiment that formed the basis of the Jacob and Monod theory was a genetic complementation experiment. If both a wild-type *i* gene and a defective *i* gene were put into the same cell, the wild-type gene dominated and turned off not only the adjacent piece of DNA but also all other pieces of DNA carrying the lactose genes in the same cell.

One infers that the *i* gene makes some product that acts through the cytoplasm to prevent the expression of the lactose genes. Thus the *i*⁻ mutations are recessive constitutives, constitutive meaning that the enzymes are made without being induced by the sugar, and the distribution of these *i*⁻ mutations defines the *i* gene. The two other controlling regions do not appear to make any product; both are defined through mutations that have only *cis* effects, changing the behavior only of the piece of DNA bearing the mutation.

The operator, conceptually the target for the *i* gene

FIGURE 1 A schematic map of the lactose (*lac*) region of the *E*. *coli* chromosome. The Figure shows the order of the regions on the DNA making up the lactose operon. The products of the three structural genes z, y, and a (β -galactosidase, permease, and transacetylase) are synthesized coordinately under the control of a repressor gene, *i*, of which the product works at the operator region,

o, to prevent the synthesis of messenger RNA (mRNA) for the structural genes. The messenger for the *lac* enzymes is synthesized, starting in the promoter region, p. The *i* product (the *lac* repressor) is made from the *i* messenger RNA, which is synthesized in the direction shown, starting at an *i*-gene promoter at the far left of the gene.

product, is a site for *cis*-dominant constitutive mutations. These o^{c} (operator constitutive) mutations permit a partial escape from the control by the product of the *i* gene, but in a complementation experiment only the structural genes physically adjacent to the mutation function.

The promoter is defined genetically by mutations that prevent the expression of all three structural genes simultaneously. These mutations, p^- , occur outside the structural genes and affect only the physically adjacent genes in the *cis* position (Jacob et al., 1964; Ippen et al., 1968). The order of genes is p-o-z-y-a. RNA for this operon is read in the direction from z to a (Kumar and Szybalski, 1969). It is generally believed, although there is no explicit biochemical proof as yet, that the promoter region provides the starting site of the RNA for the operon, read out as one piece, and thus that the p^- mutations change the rate of initiating RNA synthesis, for example, by being base changes that change the affinity of the RNA polymerase for this special region.

How does the sugar induce the enzymes? The hypothesis of Jacob and Monod was that the sugar, or an analogue of the sugar, would block the action of the repressor, prevent the attachment of the repressor to the operator, and thus leave the genes open to function. The inducer might bind to the repressor in order to make it physically unable to interact with the operator. Such a model is supported by the existence of another class of mutants of the *i* gene, mutants in which the *i*-gene product behaves as if it has lost its affinity for the inducer. Such a defective repressor should be able to bind only to the operator; a cell containing such repressors should never be induced. Such mutations, is mutations, were found: mutations to a trans-dominant uninducible phenotype. Because the *i* cells could be induced at a thousandfold greater concentration of inducer than was needed for the wild type, and because one could supply an argument based on the interaction between i^{s} and o^{c} in complementation to show that no more repressor was synthesized in the is than in the wild type, one would believe that these mutations were adequately explained as loss of affinity of the repressor for the inducer (Willson et al., 1964).

The earlier comment about the penetration and modification of a small molecule signal has an explicit realization in the lactose operon. The sugar lactose itself is not an inducer (Burstein et al., 1965). The sugar must be acted upon by β -galactosidase, which, as a transgalactosidase, transfers the galactose to some (unknown) receptor to make the inducer. Thus, the basal level of β -galactosidase is needed to provide the first molecules of inducer. A z^- cell cannot be induced. Furthermore, a γ^- cell cannot be induced by lactose. The permease must be functional to keep a high enough level of lactose in the cell to maintain the induction by the sugar. Thus, if only the "natural" inducer were known, both $z^$ and γ^- mutations woud appear to have some "regulatory" properties. These complexities are avoided by the use of unmetabolized inducers such as IPTG (isopropyl-thiogalactoside), which cannot be split by β -galactosidase.

The nature of the repressor

In 1961, a general view was held that repressors would turn out to be RNA molecules. That thought was based on an explicit experiment, a chloramphenicol inhibition experiment (Pardee and Prestidge, 1959), which was believed to show that the lac (lactose) repressor could be made in the presence of chloramphenicol and thus was an RNA molecule. The experiment is false, for several years later it could be shown that the repressor cannot be made in the presence of inhibitors of protein synthesis (Horiuchi and Ohshima, 1966). During that period, however, people talked themselves into the view that repressors were RNA molecules, overcoming the attitude that the easiest way of providing a connection between a small molecule and a nucleic-acid sequence was to use a well-shaped protein molecule. Ever since, one wondered whether the control molecule would turn out to be RNA, or protein, or both.

Further reasons for believing that the active structure required protein were that one found a variety of temperature-sensitive mutations of the *i* gene, both thermolabile (i^{TL}) and temperature-sensitive synthesis (i^{TSS}) mutations (described in detail in Sadler and Novick, 1965). More convincing, however, were the isolations of nonsense mutations in the *i* gene (changes to the nonsense codon UAG, which interrupts polypeptide synthesis). These mutations produce an inactive repressor (Müller-Hill, 1966; Bourgeois et al., 1965). Ultimately, the proof of the nature of this control substance waited on its isolation and purification as a protein.

We (Gilbert and Müller-Hill, 1966) isolated the product of the lactose *i* gene by using only that one property most central to the picture of repressor control-the repressor must bind to the inducer. The experiments were not biased by any requirement as to the composition of the repressor, nor did they depend on any model for its action. The inducer that was used is an analogue of the sugar IPTG, the best inducer known. The binding of radioactive IPTG to the repressor was followed by equilibrium dialysis: 0.1 ml samples of protein solutions were dialyzed in an ordinary dialysis sack against a solution of radioactive IPTG. Although the interaction is rather tight, a dissociation constant of 1.3×10^{-6} M, there is so little repressor in the wild-type cell that the molecule must be purified blindly before its presence can be detected in the protein solution that is put into the dialysis sack (even directly in the bacterial cell, only a few per cent excess of IPTG can be bound). After an ammonium sulfate fractionation of the bacterial extract, however, we observed material that bound IPTG. This material could be purified, and it turned out to be protein. But

was this material, which bound the inducer, relevant? It would be only if we could prove that it was, in fact, the product of the *i* gene. Even though the affinity of binding is comparable to that which one would estimate the repressor to have from an in vivo argument, this is not sufficient identification. Only the variety of mutant forms of the *i* gene yields the necessary proof. The first tests performed to show that the binding material was the *i*-gene product indicated that the material was not made in i^- cells (nonsense i^- cells in which no gene product would be made), although all the lactose enzymes were being made at a high level, and that the material was not observed in i^{s} cells. These cells differ from the uninduced wild type only by a point mutation in the *i* gene that abolishes the affinity of the repressor for IPTG. (The various mutant forms of the *i* gene were put into identical genetic backgrounds, so that unknown variations from strain to strain could not confuse the issue.) These tests, although successful, were negative in character; a better test would be to show that a modification in the *i* gene would yield a modified (but identifiable) product. We had a further mutation available, a mutant strain which induced more easily than does the wild type and which thus had a repressor with a different affinity for the inducer. In vitro, this mutant repressor bound IPTG with a different dissociation constant than that of the wild type.

More recently, a number of further proofs have appeared. Ohshima et al. (1968) have shown that temperature-sensitive mutations of the *i* gene produce an IPTG-binding protein that has a different temperature stability than does the wild type. Furthermore, there are mutations in the *i* gene that change the amount of gene product, both as estimated from in vivo tests and as determined physically. The amount of repressor made by the wild-type cell is very small, about 0.002 per cent of the cell's protein: about 10 copies per haploid genome. Benno Müller-Hill (Müller-Hill et al., 1968) sought and found mutant forms of the *i* gene which made more repressor (i^{Q} , Q for quantity, mutations). The original i^{Q} makes 10 times more repressor. The mutation lies at the end of the i gene farthest from the z gene (at the left in Figure 1); the *i* gene is read from left to right (Miller et al., 1968; Kumar and Szybalski, 1969); and so we believe that this i^{Q} mutation is most likely a promoter mutation, producing a tenfold faster synthesis of *i*-gene messenger.

The technology has now reached the point at which the *lac* repressor is an easily obtainable protein. The very low level in the wild-type cell, 0.002 per cent of the protein, has been raised more than 1000 times. The i^{Q} mutation raised the level by a factor of 10, to 0.02 per cent (or 0.05 per cent in a diploid). To get still more repressor, we put the i^{Q} on a defective phage, a derivative of phage λ that carries the *lac* genes as a replacement of the late phage functions. This phage can be triggered by heat to multiply within the cell.

Several hundred copies of the phage genome are made, but the phage is unable to lyse the cell. These multiple copies of the *i* gene make, in practice, about 25 times more repressor, so these cells are harvested with 0.5 per cent of their protein *lac* repressor. Very recently, Jeffrey Miller (unpublished) isolated a new mutant, an *i* ^{super Q} that makes five times more repressor than does the *i*^Q parent. This is 50 times the basal level. When this mutation is placed upon the phage, cells can be harvested with 2.5 per cent of their protein *lac* repressor. This is a yield of several grams per kilogram of cells. Large amounts of repressor have been made in Cologne, and work on the amino-acid sequence is being started there.

The material is purified easily by ammonium sulfate fractionation, elution from a phosphocellulose column at pH 7.5, and, if necessary, a DEAE-column step. The *lac* repressor is an acidic protein (but it has a basic region capable of binding to phosphocellulose at neutral pH). There is nothing unusual about its amino-acid composition. It is a tetrameric protein, 150,000 in molecular weight, with four identical subunits of 38,000. It binds four molecules of IPTG. How does it work?

The repressor binds to operator DNA

Ultimately to understand how a repressor works, we wish to know the physical target and how the interaction of the repressor with that target blocks protein synthesis. The experiments that are presently feasible are to examine the interaction of the repressor with candidates for the operator. One can show that the lac repressor binds specifically to the lac operator DNA (Gilbert and Müller-Hill, 1967; Riggs et al., 1968). Such an experiment is done most easily by using DNA from the defective variant of phage λ that carries the lac genes. This phage will yield DNA molecules of a uniform size, each about 30×10^6 in molecular weight and each carrying one copy of the *lac* operator. (This is a gene dosage about 70 times higher than would be true for bacterial DNA. Nonetheless, a 3γ /ml solution of such DNA is only 10⁻¹⁰ M in operators.) The DNA sediments at 40 S; the lac repressor itself sediments at 7 S. Thus, if we mix radioactive lac repressor, made by purifying the lac repressor protein from radiocatively labeled E. coli, with the purified phage DNA, and sediment the two together on a glycerol gradient, if the protein binds to the DNA, it obviously sediments faster, moving in a band with the DNA.

Such experiments can show that the *lac* repressor binds only to DNA carrying the *lac* region. If one uses phage DNA that does not have the *lac* region, the protein will not bind, nor will it bind to denatured *lac* DNA. But far more specifically, if the phage DNA carries an o^{e} mutation, a point mutation, or a small deletion mutation in the operator, that mutation will abolish or weaken the binding. Thus we infer that the protein is binding only to a single sequence that occurs only in the operator (as defined genetically).

The physical size of the objects are shown in Figure 2. The phage DNA molecule is $15 \mu \log$; the entire *lac* region is $2 \mu \log$; but we are implicating only one point along the molecule at which a protein, about 70 Å across, binds.

FIGURE 2 The relative sizes of the *lac* repressor, the *lac* genes, phage lambda DNA, and the lambda repressor. The phage DNA is represented as it might be free in solution, with a *lac* repressor bound to the *lac* operator and with two lambda repressors bound to the phage operators.

The phage λ repressor

Phage λ makes a repressor that turns off the early genes of the phage. Mark Ptashne (1967a) isolated this repressor. It is a protein about 30,000 in molecular weight, the size of the subunit of the *lac* repressor. This material has not yet been completely purified physically, but it has been purified radiochemically. This protein binds to two specific regions on phage λ to block two operons (Ptashne, 1967b; Ptashne and Hopkins, 1968). Figure 3 shows this region of the phage. The gene that makes its repressor is called the C_I gene, and its product binds to two operators (again identified genetically by operator-constitutive mutations), which, in turn, can be shown to prevent the binding of the λ repressor controlling operons that run out in opposite directions along the λ DNA. These repressors are represented to scale in Figure 2.

Induction in vitro

Although for λ the story stops with the specific interaction of the repressor with the operator, the *lac* repressor can be pushed further—what does the inducer, IPTG, do to the binding? It prevents the binding. Or, more specifically, if the repressor is first bound to the DNA, then the inducer, IPTG, will cause the complex to fall apart. These experiments directly support the notion that the repressor, on binding to the operator sequence on the DNA, prevents the functioning of the promoter. The inducer weakens the binding to the operator, the repressor comes off, and the operon can function. We do not know explicitly, however, that the repressor blocks (sterically) the attachment of the RNA polymerase to the promoter.

The affinity of the repressor for the operator

We estimated how tightly the repressor interacts with the operator by asking how low a concentration of components could be used before the complex fell apart as the DNA moved down the centrifuge tube. That estimate for the dissociation constant is 2×10^{-12} M, or tighter, in 10^{-2} M Mg⁺⁺ and 10^{-2} M monovalent salt. At higher salt concentrations, the affinity weakens to 10^{-10} M in 0.15 M KC1. These salt

FIGURE 3 Schematic map of the genes of phage lambda. On the right half of the phage genetic map lies the gene for the phage repressor, C_I , and the early genes that function when the repressor is inactivated. One operon, read to the left, contains genes N (early positive control) and a set of genes---beta, exo (early positive control), xis (excision), int (integration)--involved in recombination

and in the integration of the phage DNA into the host chromosome. To the right of C_I , another operon is read to the right; this contains genes O and P involved in phage DNA replication. Gene Q turns on late functions, such as R(lysozyme), and the other late genes.

concentrations span the physiological range and yield affinities in the range of in vivo estimates.

Such in vivo estimates can be made by arguing that the rate of enzyme synthesis depends only on the number of operators free from repressors. If the concentration of free operators is governed by a mass-action formula:

$$\left[\mathsf{O}\right]\left[\mathsf{R}\right] = \mathsf{K}\left[\mathsf{O}\mathsf{R}\right],$$

relating the concentrations of free operators and repressors to the concentration of complexes of operators with repressors, one can estimate K from the statements that there are about 10 repressors per cell (and thus $[R] \sim 10^{-8}$ M) and that the basal level of enzyme synthesis is one 1000th of the full level ([O]/[OR] is 1/1000). The dissociation constant, K, would then be on the order of 10^{-11} M. (The argument depends on the basal level's reflecting of the maximal amount of repression. If the basal level is caused by some escape process, then the actual affinity could be much higher.)

A far more accurate approach has been developed and exploited by Arthur Riggs and Suzanne Bourgeois (Riggs et al., 1968, 1970). They discovered that the repressor can cause the trapping of DNA molecules on cellulose-nitrate filters. In the absence of repressor, the entire native DNA molecule passes through the filter. When one repressor molecule binds to a DNA molecule, that DNA molecule adheres to the base of the cellulose-nitrate filter. (Possibly, because the repressor protein itself binds to the filter, the DNA molecule is glued to the filter material by the repressor.) By labeling the DNA and varying the concentration of repressor, they can observe a saturation curve and estimate a binding constant. Their estimates are now that the dissociation constant is 10^{-13} M in low salt (0.01 Mg⁺⁺, 0.01 KC1, 0.01 tris pH 7.4, 5 per cent DMSO). One can measure such high affinities directly because of the amplification resulting from the size of the DNA molecule, the binding of one repressor being measured by the fixation of 30×10^6 molecular weight of DNA (or 10⁵ phosphates). Gene concentrations in the range of 10^{-14} M are easily measurable.

The in vitro and in vivo estimates for the affinity are so high that they raise an immediate question about the rates of formation and dissociation of the repressor-operator complex. The dissociation constant might be thought of as the ratio of two rates—the ratio of the rate of decay of the complex k_d, to the forward rate of formation, k_f : $K = k_d/k_f$. The repressor must diffuse up to the DNA, must find a particular point on the DNA molecule, and might have to adjust its shape or wait for the operator to assume the correct shape before the complex can form. This over-all process cannot go faster than the repressor can diffuse up to the neighborhood of the operator. If we are generous with our estimate, the diffusion limit for a molecule the size of the *lac* repressor to hit the surface of a 20 A sphere would be one or two times 10⁹ per molar second. Thus, one would expect the decay rate to be about 10^{-4} per molar second, if the dissociation constant is to be 10^{-13} M. A characteristic decay of 10^{4} seconds (which is several hours) would be quite an appreciable time for the components to stay together before the complex falls apart, but this is an immediate consequence of the tight binding.

Is it possible to detect this slow decay experimentally? Yes, it has been seen by Riggs and Bourgeois (unpublished) using the filter-binding assay. They complexed the *lac* repressor to radioactive *lac* DNA. Then they mixed that solution with a great excess of unlabeled *lac* DNA. As the repressor came off a labeled molecule and went onto an unlabeled one, that labeled molecule no longer could be trapped on the filter. By filtering samples of such a mixture at different times, they could observe the loss over time of the label that could be trapped, and this loss reflects directly the decay of the original repressor-operator complex. Their actual estimate for the half-time is 30 minutes, a rate of about 5×10^{-4} per second. The complex is indeed slow to decay in vitro.

The nature of induction

This slow decay immediately raises a problem, because we know that in vivo one can induce promptly on adding the inducer, with no detectable lag before the inducer-triggered event. If the kinetic process of induction requires the repressor to fall off the operator and then to be caught by the inducer, one should not be able to induce any faster than the repressor can leave the operator: a 30-minute delay. There is no reason, however, to accept this picture unless we wish to believe that the inducer and the operator use the same site on the repressor, for only then must competition be the method of induction.

If the inducer and operator use different sites, the induction can be a two-step process in which the inducer first binds to the repressor stuck to the DNA and only afterward does that complex dissociate. These two models are shown in Figure 4. Although they can have indistinguishable equilibrium properties, the kinetics will be different. In one model, the natural decay of the repressor-operator complex is unaffected by the inducer, which blocks only the rate of reformation of the complex; in the other, the inducer interacts directly with the repressor-operator complex, and binds to and changes slightly the repressor moiety of the complex, producing a fast decay of that complex. Such a change in the decay can be seen experimentally in vitro. Riggs and Bourgeois (personal communication) have examined the decay of the repressor-operator complex in the presence of inducer and see a faster decay. There are also compounds that are competitive inhibitors of induction-molecules analogous to the sugar but that prevent induction. Such molecules, like ONPF (ortho-nitro-phenyl-fucoside), bind to the repressor

FIGURE 4 Two models for induction. Alternate possibilities for the induction are shown. The inducer ultimately removes the repressor from the DNA so that the genes can function. This process could be thought of as either (A) the equilibrium between the repressor and the operator being perturbed by the free repressor's binding to the inducer, so that it cannot return to the operator, or (B) the inducer's binding to the repressor while still on the operator and perturbing the structure of the repressor, so that the binding to the operator is weakened.

and, in fact, prevent the dissociation: experimentally, one sees a slower decay for the complex. We can understand these effects by thinking of the bound IPTG changing the repressor so that its affinity to the DNA is less, and the binding is weaker, leading to a faster decay. With ONPF the binding is actually stronger, the decay slower. Because the inducer changes the decay rates, the second model in Figure 4 must be correct: a ternary complex is actually formed through which the inducer pushes the repressor off the operator.

There is a catch in these numbers because they require that the forward rate of formation of the complex be 5×10^9 per molar second. This is, in fact, a very high rate constant. Riggs and Bourgeois (personal communication) have also measured this rate directly by diluting the components to the level at which the complex takes tens of minutes to form. They observe, over these long times, a rate consistent with this figure of 5×10^9 per molar second. This rate is so fast that one begins to expect that the critical object up to which the repressor diffuses will be trapped eventually in some region on the DNA molecule appreciably bigger than the operator. The repressor may need to hit only within several thousand Ångstroms of the operator and then can move along the DNA to find the correct region. This is not unreasonable, because the repressor has a general affinity for DNA in that it can stick to the phosphate backbone. (This affinity in the case of the *lac* repressor can be enhanced by leaving out the magnesium ion to the extent that the nonspecific binding to the phosphates completely dominates the specific binding to the operator.)

The picture of induction as passing through a ternary complex would argue that there should be an interaction between the repressor-inducer complex and the operator. One should be able to detect the interaction between the "fully induced" form of the repressor and operator DNA. So far this has not been seen in vitro, but in vivo we can estimate an affinity. If there is a residual affinity of the repressorinducer complex for DNA, then, if there is enough of that complex in the cell, it will bind to the operator and keep the genes from functioning. This actually happens in vivo in those mutants that make more and more repressor. The i^{Q} is inducible only to 65 per cent of the full rate; the $i^{\text{super }Q}$, only to 25 per cent (Jeffrey Miller, personal communication). The argument that the rate of expression should be proportional to the concentration of free operators can be used to show that the affinity of the operator for the fully induced complex is a factor of 2×10^4 weaker than that for the uncharged repressor. In the wild-type cell, these numbers mean that the amount of repressor which is 10³ times the dissociation constant, and which keeps the operator closed 99.9 per cent of the time, is only one 20,000th effective after full induction and keeps the operator closed 5 per cent of the time.

The nature of the operator

We do not yet know the structure of the operator or the details of the interaction between the operator and the repressor. The experiments so far show only that doublestranded DNA is required, and that the interaction sees either the outside of the native helix or requires the participation of both strands. There is enough information available, visible in the large groove, to distinguish all the base pairs from the outside when the DNA is double-stranded. It is not necessary to separate the strands to see the hydrogen bonds used in the Watson-Crick pairing in order to read a sequence. How big is the operator? To the extent that this region is a stretch along the DNA to which a protein molecule the size of one subunit of the lac repressor (38,000 mol. wt.) or of the size of the lambda repressor (30,000 mol. wt.) can bind, it can only be between one and two turns of the DNA molecule (35 to 70 Å, 10 to 20 bases).

There is a general argument as to how large such a region must be, based simply on the realization that there are very few lac repressors in an E. coli cell. These repressors bind to one site on the *coli* DNA with very high affinity. If they find other regions of the DNA with equally high affinity, they will be sopped up and made unable to function. This means that the region to which they bind must be unique in the chromosome (3 \times 10⁶ base pairs) and thus must have *at* least the specificity of 12 bases. We might think of a region 12 to 15 bases long, 40 to 50 Å long, associated with a binding energy in the range of 16 to 18 kilocalories. These are not unreasonable numbers to be associated with one another. An interaction with this specificity, "seeing" 12 to 15 bases, must make about 12 to 15 contacts; to the extent that each contact yields between 1 and 2 kilocalories, the energetics (i.e., the tightness of binding) and the specificity are commensurate. The change in binding energy involved on induction, a change by 2×10^4 in affinity, or 6 kilocalories, is brought about by the binding of up to four IPTGs, each one of which can bind with about 8 kilocalories. Clearly, there is enough free energy available in the binding of the IPTGs to produce a distortion in the repressor capable of weakening its total binding to the operator by 6 kilocalories.

Phenotypic complexities

Several phenomena are explained by our knowledge that the lac repressor is a tetramer (see Müller-Hill et al., 1968). One of these phenomena is the existence of dominant i^- mutations (i^{-d}) . Although the original defining characteristic of the *i* gene was that constitutive mutations were recessive, a further class of point mutations in the *i* gene was found a few years ago and were later shown to be trans-dominant constitutives. These mutations, however, are recessive to the i^{Q} : 10 times more repressor overcomes the effect of the mutations. The i^{-d} can be interpreted as having bad subunits which join together to form an IPTG-binding, but inactive, repressor and which can mix with good subunits to form hybrid, inactive molecules. The bad subunits distort the good, so that the molecule will no longer bind to DNA. Another complementation effect is that the *i*^s which makes a repressor that cannot be induced and which dominates the i^+ is dominated in turn by the i^Q . In an environment that contains a great excess of good subunits, the is subunits will be tied up in hybrids with one i^{s} and three i^{+} subunits, and these hybrids will be inducible: their affinity for the operator can be weakened by IPTG.

Possible implications for higher cells

What aspects of these repressor control systems might appear again in higher cells? The control in *lac* is exercised by a small number of molecules, made by a gene that appears to run at a fixed rate under the control of a promoter changeable only by mutation. These control molecules, acidic proteins, interact with high affinity with a specific site on the DNA. These properties may appear again, but the volume of cells and the amount of DNA increase about 1000 times; thus, the specificity and affinity should also increase 1000 times. The control is efficient. One lac repressor of 150,000 daltons controls about 4 \times 10⁶ daltons of DNA; the control material bound to the DNA is about 3 per cent by weight of the genes controlled. Phage lambda provides a still more vivid example of efficiency, because 30×10^6 daltons of DNA are controlled by a repressor constituting only a few tenths of one per cent by weight of the DNA that is controlled. This is a better analogue for higher cellscontrol through elements of high specificity but there, in the chromosome, in trace amounts. Not only does lambda provide an example of efficiency; the control here is more sophisticated than in the simple case of *lactose*.

Eisen et al. (1968) have shown that there is a specific separate control of the amount of lambda repressor. While the repressor is present, it shuts off the two operators controlling the two early operons of the phage. Once the repressor has been inactivated, however, and the operon on the right begins to run, no further C_I repressor can be made. The most recent experiments by Harvey Eisen suggest that the first product made by this operon is a repressor of the repressor (C^{repressor}), which turns off any further synthesis of the C_I repressor. The phage can have two stable intracellular states which can be displayed if the phage genes that kill the cell are removed. Either it makes the C_I and never the C^R product, or it makes the C^R (and other enzymes from the righthand operon) and not the C_I.

There are also two steps of positive control. The operon that runs to the left makes the gene N product that is required for the high-level expression of all the early phage functions. The N product is a positive control element; if the left-hand operator is open, the N product turns on a further set of genes to the left. These are involved in recombination, integration, and excision functions. If the right-hand operator is open, the N product enhances the level of gene products made to the right. These are the genes involved in phage DNA synthesis, which permits phage to multiply. There is a further separate control on the late phage functions. The N product also turns on gene Q, which itself turns on the late functions such as coat proteins, tail structures, and a lysozyme. Here, indeed, is a model of sufficient complexity, put together out of simple control loops, to provide an example of what might be going on in a higher cell.

84 Two Sequence-Specific DNA-Protein Recognition Systems

A. D. KAISER

LYSOGENY FOR bacteriophage λ depends on the addition of viral DNA to the DNA of its host and removal of the viral DNA at a later time. Many temperate bacteriophages, a number of episomal bacterial genetic elements (Campbell, 1969), and possibly DNA tumor viruses (Dulbecco, 1968) attach to their host's chromosome. The addition and removal of λ DNA are made with such high precision that neither phage nor bacterium gains or loses base pairs in the process, except in the rare instances of transducing phage production, in which a fragment of the viral DNA is excised with an adjoining fragment of bacterial DNA. A complete cycle of addition and removal requires two different DNA joining and cutting steps, both of which are sequence-specific and require phage-induced proteins. These steps provide us with examples of DNA-protein recognition amenable to experimental exploration, and the purpose of the present paper is to give a molecular description of those steps.

Particles of phage λ contain a single linear DNA molecule, 50,000 base pairs long. How is this molecule added to the hundred-times-larger circular molecule of bacterial DNA? The correct solution was proposed by Campbell (1962, 1969); he suggested that a linear molecule of phage DNA first joins its ends to become a circle, then recombines with the circular bacterial DNA to form a single large circle, as illustrated in Figure 1.

When lysogenic bacteria produce active phage, these processes are reversed, in a formal sense. Phage DNA is excised from the chromosome, and, after replication, linear DNA molecules are encapsulated in the new phage particles. The two steps depicted in Figure 1 involve the joining and the cutting of DNA molecules, as follows. In the forward direction of Step 1, two ends of one infecting DNA molecule join and, in the reverse direction, a newly synthesized DNA molecule is cut to create ends. In the forward direction of Step 2, two circular molecules are cut and joined to each other. In the reverse direction of Step 2, one DNA molecule is cut in two places, and the four ends join in pairs to recreate a molecule of phage DNA and a molecule of bacterial DNA. The base sequence-specificity inherent in the DNA-protein recognition in both steps is very high. Cutting in Step 1 occurs at just one place in the phage DNA molecule of 5×10^4 base pairs. The forward direction of Step 2 occurs at just one place in the phage DNA molecule and at just one place in a bacterial DNA molecule of 5×10^6 base pairs. We turn now to a discussion of the molecular events.

PHAGE DNA ENDS, THE FIRST RECOGNITION SYSTEM DNA molecules extracted from λ phage particles are linear. If these linear molecules are heated to about 70° C and allowed to cool slowly, they spontaneously join their ends and become circles (Hershey et al., 1963; Ris and Chandler, 1963; MacHattie and Thomas, 1964). The joining of ends is specific, for λ DNA will not join to other types of DNA molecules. If circular molecules are heated to 70° C (λ DNA retains its native double-stranded structure up to 90°) and cooled rapidly, they open into linear structures. The structural basis of the reversible joining and separating is a pair of single strands which protrude from the two ends of a molecule of λ DNA (Wu and Kaiser, 1968; Wu, manuscript in preparation) as shown in Figure 2. The two protruding single strands have complementary base sequences which

FIGURE 1 Changes in DNA structure during lysogenization by phage λ . A line represents a double-stranded DNA molecule. The thick line represents λ DNA; and the thin line, bacterial DNA.

A. D. KAISER Department of Biochemistry, Stanford University School of Medicine, Stanford, California

FIGURE 2 Joining and cutting of phage DNA ends. The ends of the strands of the linear phage DNA molecule are labeled 3' and 5' to indicate the hydroxyl group on the terminal nucleotide that is *not* engaged in phosphodiester linkage. Both 5' termini carry phosphate groups, and both 3' termini are free hydroxyl groups. Note that the circular DNA molecule at the top is held together by base pairing only and that the one below is held together by base pairing and covalent bonds.

join to each other to form a helix of base pairs. The cohesive ends "melt" at a lower temperature (65° C) than does the rest of the molecule (92° C), because only 12 base pairs hold the ends together, whereas 50,000 pairs hold the rest of the molecule. Cohesive ends of this type are not unique to λ DNA. They have been found in nine other bacteriophages and in the DNA isolated from the mitochondria of yeast.

Joining of cohesive ends can be viewed as a DNA-DNA recognition process and is interesting as such. Ends join rather slowly in vitro. For example, at physiological temperature, pH, and ionic strength the half-time for joining is about one hour (Wang and Davidson, 1968). It seems that the reaction that limits this rate is not the diffusion of ends toward each other, but the base pairing and stacking that follow (Wang and Davidson, 1966). In vivo, however, the ends join about 10 times faster, suggesting the existence of an intracellular catalyst.

When the ends of a molecule of λ DNA are joined by base pairing, the 5' phosphate end of each strand is adjacent to its own 3' hydroxyl end (Wu and Kaiser, 1968). In vitro, the enzyme DNA ligase will close both nicks with covalent bonds to form a double-stranded circular molecule with no interruptions in the polynucleotide chains (Gellert, 1967). In vivo, DNA of the infecting phage circularizes and is covalently closed within five minutes after injection. DNA ligase is present in the host cells before infection (Gellert, 1967; Olivera and Lehman, 1967a), so it is likely that the ends cohere and are sealed with covalent bonds by DNA ligase in vivo, but there is no direct evidence on the point. DNA ligase is not sequence-specific. It requires only a 3'OH adjacent to a 5'P held in the proper positions by a complementary strand.

After an infecting DNA molecule circularizes, it may add to the host DNA to create a lysogenic bacterium or it may replicate manyfold, produce new, mature, phage particles, and lyse the infected cell. Cohesive ends of mature phage DNA play no further role in the lysogenization process. On the other hand, when new phage particles are produced, new cohesive ends are generated. The structures of the intermediates in λ DNA replication are not yet firmly established, although there is evidence for replicating circular molecules (Young and Sinsheimer, 1967; Tomizawa and Ogawa, 1968) and for circular molecules with linear polymeric tails (Gilbert and Dressler, 1968; Eisen et al., 1968; Kiger and Sinsheimer, 1969). Neither of these structures would be expected to have cohesive ends, and the failure of extracted intracellular λ DNA to infect helper-infected bacteria suggests that none of the replicative intermediates have the mature phage cohesive ends. In fact, new cohesive ends appear only with the formation of new phage heads, complete with their protein membrane (Dove, 1966; Mackinlay and Kaiser, 1969). Thus, the act of recognition that picks out the proper base sequence and transforms it into a cohesive end is not performed until the end of a cycle of virus multiplication, coupled to the formation of phage heads.

A genetic and a chemical argument demonstrate the sequence-specificity involved in creating phage DNA ends. The joined cohesive ends are situated on the phage recombination map between genes A and R (Kaiser and Inman, 1965). Many different deletion mutants of λ have been isolated; these have included, in one mutant or another, all the known genes of λ . (Incomplete, and therefore defective, phage genomes can be preserved and replicated as prophage, which is one reason that $\boldsymbol{\lambda}$ and its relatives are useful genetic tools.) Some deletions remove gene A but not R; others remove gene R but not A; and some, both A and R. Only the first two classes of deletion DNAs can be packaged into phage particles (Kayajanian and Campbell, 1966; Kayajanian, 1968). Members of the third class, deleted for A and R and, therefore, for the intervening DNA, can be propagated as defective prophage, but cannot be matured into complete phage particles, presumably because they lack the proper base sequence.

The chemical argument for specificity is that the cohesive ends have a defined base sequence. Part of the sequence has been determined by the limited addition of nucleotides catalyzed by *E. coli* DNA polymerase and is summarized in Figure 3. Of the 12 base pairs in the cohesive ends, 10 are guanine-cytosine (G-C) and two are adenine-thymine (A-T). Part of the sequence is a pure G-C run of eight base pairs. The existence of a defined sequence implies that all molecules of λ DNA have the same sequence and suggests that the bases in the cohesive ends themselves are part of the recognition sequence. Were this

FIGURE 3 Base sequence at the phage DNA ends. The ends are shown cohered to each other. The r-strand has its 5' terminus at the right end of the λ DNA molecule, drawn as the genetic map is conventionally drawn with the R gene at the right end, and the ℓ -strand has its 5' terminus at the left end. Brackets around the A-T pair and two G-C pairs in the center of the Figure indicate that their orientation is not known, that is, whether A or T is in the ℓ -strand.

not so, one would have expected heterogeneity in the cohesive sequence between different λ molecules.

The basic chemical event in creating phage DNA ends may be the introduction of a pair of single-stranded breaks in the proper places in a circular or linear, polymeric DNA molecule. The a priori probability that a particular sequence of 12 bases will occur in a random sequence of 5×10^4 base pairs, the length of λ DNA, is 10^{-2} . Therefore, it is improbable that the cohesive-end sequence repeats elsewhere in the molecule. It should be noted that the single-stranded break in phage $\Phi X174$ replicative form II DNA, the product of another DNA-protein recognition, is also between two G-C pairs (Knippers et al., 1969). It has been suggested that G-C runs might have a three-dimensional shape that facilitates their recognition (Szybalski et al., 1966; Dove, 1968).

PROPHAGE DNA ENDS, A SECOND RECOGNITION SYSTEM The addition of a circular molecule of λ DNA to its host DNA and the subsequent removal of the viral DNA utilize another recognition system with at least four specific elements. Two are specific base sequences, one in λ DNA, situated 28,700 base pairs from the left cohesive end (Parkinson, 1969) and indicated by P·P' in Figure 4. Another is a base sequence in *E. coli* DNA, situated approximately 12,000 base pairs from the galactose operon (Kayajanian and Campbell, 1966) and indicated by B·B' in Figure 4. The two remaining elements are gene products, probably proteins, specified by the *int* (for integrate) and *xis* (for excise) genes of λ .

An overview of the operation of this system is presented first, followed by a summary of the supporting evidence; finally, a molecular mechanism is suggested.

The *int* protein recognizes the $P \cdot P'$ and $B \cdot B'$ sequences in phage and *E. coli* DNA. As a consequence, both sequences are broken at the dots, and a reciprocal transfer occurs, P

joining to B' and B joining to P', inserting the phage DNA into the bacterial DNA to form one large circular molecule. An important feature of the system is that *int* protein cannot recognize the two new sequences at the ends of the prophage $B \cdot P'$ and $P \cdot B'$, so the adduct of viral and host DNA is stable. A combination of the *xis* protein with the *int* protein can, however, recognize the new sequences. Acting together, they catalyze a breaking of the $B \cdot P'$ and $P \cdot B'$ sequences at the dots, and again a reciprocal transfer occurs. Now P rejoins to P' and B to B', recreating a circular molecule of λ DNA and a nonlysogenic *E. coli* chromosome. According to this scheme, the reaction goes toward insertion or toward excision, depending on whether *int* protein alone or *int* and *xis* proteins are present.

The scheme just outlined might seem to violate the principle of microscopic reversibility, because different catalysts have been proposed for the forward and reverse directions. Note, however, that it is a genetic scheme and not a complete chemical reaction. It seems likely that chemi-

Lysogenic Bacterium

FIGURE 4 Insertion and excision of λ DNA into and from bacterial DNA. The thick line represents phage DNA, and the thin line, bacterial DNA. P and P' represent the left and right recognition base sequences in λ DNA. B and B' represent the left and right recognition sequences in bacterial DNA. The dots in P·P' and B·B' indicate the places where the sequences are cut and rejoined. R and A are the phage genes on either side of the cohesive end sequence, which is joined by covalent bonds in all the structures of this Figure.

cal energy would be required for the joining reactions. One kind of DNA ligase is known to employ nicotinamideadenine dinucleotide (NAD) and another adenosine triphosphate (ATP) (Olivera and Lehman, 1967b; Weiss et al., 1968). Hydrolysis of the energy donor coupled to the transformations of DNA might drive the reaction to completion in both directions. There may be an analogy with glycogen metabolism in which different enzymes, utilizing different small molecules, catalyze either extensive glycogen synthesis or extensive breakdown. We turn now to examine the evidence on which this scheme is based.

The int gene product

The first element in the recognition system, the *int* gene, is defined by missense and nonsense (amber) point mutants and by deletions. *Int* mutants cannot lysogenize although they can establish immunity. They cannot perform the insertion step (Zissler, 1967; Gingery and Echols, 1967; Gottesman and Yarmolinsky, 1968). In the presence of a coinfecting *int*⁺ phage, an *int*⁻ mutant can insert. This complementation implies that an *int*⁻ mutant has normal recognition sequences but is unable to synthesize a diffusible protein, probably an enzyme. Once installed by complementation as a prophage, an *int*⁻ mutant cannot excise, again unless an *int*⁺ phage is also present to provide active *int* protein. Thus, the product of the *int* gene is a cytoplasmic protein necessary for insertion and excision.

The *int* protein is sequence-specific. Phage lambda, phage 21, and phage $\Phi 80$ occupy different sites, as prophage, on the chromosome of *E. coli* K12. Neither $\Phi 80$ *int*⁺ nor 21 *int*⁺ can complement a λ *int*⁻ and cause it to lysogenize (Signer and Beckwith, 1966; Gottesman and Yarmolinsky, 1968). The λ , $\Phi 80$, and 21 *int* proteins, therefore, each recognize different sequences. Deletion mutations place the *int* gene within 750 base pairs of the sequence recognized by its protein product.

The xis gene product

The xis gene is defined by missense, nonsense, and deletion mutations. Xis⁻ mutants lysogenize at normal frequency, but they cannot excise (Guarneros and Echols, 1970; Kaiser and Masuda, 1970a). For this reason, they are trapped in the bacterial chromosome. Xis⁻ mutants can, however, excise if an xis⁺ phage is present, showing that the xis gene product is diffusible. In particular, an xis⁻ mutant can excise if an *int*⁻ mutant is present, demonstrating that an *int*⁻ mutant makes an effective xis gene product. Xis⁻ mutants can also be complemented by a deletion mutant, called bio 16A, which terminates in the *int* gene, but not by another deletion, called bio 7–20, which extends 1750 base pairs farther on. Therefore the xis gene lies very close to the *int* gene and to the base sequence on which it functions. This clustering of the specific base sequence, the *int*, and the *xis* gene is yet another example of the clustering of genes with related functions that characterizes bacteriophage λ (Dove, 1968). As is the *int* protein, the product of the *xis* gene is sequence-specific. For example, the *xis* protein of phage 21 will not work with the *int* protein of λ on the sequence at the ends of prophage λ , nor will the 21 *int* protein work with the *xis* protein of phage λ on the ends of prophage λ (Kaiser and Masuda, 1970b).

The recognition sequences in E. coli and λ DNA

The third element in this recognition system is a sequence of bases in *E. coli* DNA, called *att* λ for attachment λ , and represented in Figure 4 by B·B'. The sequence is situated between *galE* and *bioA* (genes in the galactose and biotin operons) on the *E. coli* map, because λ can attach to F' *gal bio*, which carries just this portion of the map. Deletion of the chromosomal region containing *att* λ reduces the frequency of λ lysogenization by at least 100 times (Gingery and Echols, 1968; Shapiro and Adhya, 1969; Adhya, unpublished); therefore the base sequence *att* λ is specific. A number of other specific prophage attachment sites have been mapped in *E. coli*; *att*80 and *att*21, for example, are near the tryptophan operon, and *att*424 is near the histidine operon (Jacob and Wollman, 1961).

The fourth element in the recognition system is a specific sequence of bases in λ DNA, represented by P·P' in Figure 4. If a part of this sequence is deleted, as in the mutant $\lambda b2$, a phage is produced which multiplies normally, but cannot lysogenize (Zichichi and Kellenberger, 1963). Unlike λ *int*⁻, the lysogenization defect in $\lambda b2$ cannot be overcome by a diffusible product of a coinfecting $\lambda b2^+$ (Campbell, 1965). By appropriate maneuvers $\lambda b2$ can be made a prophage. But, as a prophage, it cannot be excised, and, again, its excision defect cannot be complemented by coinfecting $b2^+$. Thus $\lambda b2$ possesses a structural defect for insertion and excision, which, because some of its DNA has been deleted, is believed to be the loss of part of the recognition sequence.

Locating the recognition sequence in λ DNA

Rare mistakes in excision give rise to λ gal or λ bio transducing phage (Campbell, 1962, 1969). As diagramed in Figure 5, the two transducers excise one of the prophage ends with adjacent bacterial genes. Lambda gal contains the left end of the prophage, indicated by $\mathbf{B} \cdot \mathbf{P}'$ in Figures 4 and 5, and λ bio carries the right end, $\mathbf{P} \cdot \mathbf{B}'$. A λ gal bio has been constructed in two steps and contains a pure bacterial attachment site, $\mathbf{B} \cdot \mathbf{B}'$ (Kayajanian, 1968). This λ gal bio carries no phage genes apart from the recognition sequence for the cohesive ends and the recognition sequence for insertion-excision; the rest of its DNA is bacterial. It can be replicated as a prophage and excised and incorporated into phage particles in the presence of a coinfecting normal λ .

The DNA from λ gal and λ bio phages can be used to locate the junction between phage and bacterial DNA. (This junction is represented by a dot in the symbols $B \cdot P'$ and $P \cdot B'$.) A DNA-DNA hybrid between λ gal and λ is constructed, then examined in the electron microscope. Transition from a double-stranded, λ/λ , structure to a single-stranded, gal/ λ , structure indicates the junction. Hradecna and Szybalski (1969) have found the position of the transition point to be the same in all λ gal and λ bio, namely, 0.57 of the length of a molecule of λ DNA, measured from the left cohesive end. The invariance of this distance means that λ DNA always breaks at the same point, within a measurement error of about 250 base pairs, when it inserts into the *E. coli* chromosome.

The bacterial and the phage recognition sequences are different, as is most clearly seen from the properties of λ gal and λ bio, which have recognition sequences that are part bacterial and part phage. Lambda gal lysogenizes with low efficiency and the defect is structural, because it cannot be complemented in trans, that is, the function cannot be supplied by a second phage (Weisberg and Gottesman 1969). The same holds for λ bio (Manly et al., 1969). If the phage and bacterial recognition sequences were identical, there would be no structural defect in either λ gal or λ bio. Because both are defective, there must be sequence recognition on both sides of the exchange point, and phage and bacterium must differ in both.

If the *int* and *xis* products recognize and recombine two specific base sequences, it should be possible to observe

FIGURE 5 Origin of λ gal and λ bio transducing phage. The thick line represents λ DNA; and the thin line, bacterial DNA. B, P, R, and A are defined in the legend of Figure 4. The two braces indicate the DNA segments which are excised from the chromosome and joined at their ends to produce λ gal and λ bio. The mechanism that produces these rare, abnormal excisions is not known.

int-xis catalyzed recombination between two phage which carry the proper recognition sequences. The experimental problem in observing this effect is that both E. coli and λ specify general recombination systems the activity of which would hide attachment-site specific recombination. Using a bacterial mutant that lacks the general recombination system, however, Weil and Signer (1968) and Echols, Gingery, and Moore (1968) demonstrated recombination between two phage mutants also deficient for the phagespecified general recombination system. The observed recombination has the properties expected of the integrationexcision system. First, it is site specific: it occurs only in the region containing the insertion exchange point. Second, it is reciprocal: single, mixedly-infected bacteria tend to produce equal numbers of the two reciprocal recombinants (Weil, 1969). Using this type of recombination in an elegant way, Echols (1970) has delineated the specificity of the int and xis products. Some of his data are reproduced in Table I. It shows that recombination in the forward, or insertion,

TABLE I Recognition Specificity of Int and Xis Determined by Phage Crosses

1. "Insertion" recombination: $P \cdot P' \times B$	$\mathbf{B} \cdot \mathbf{B}' \to \mathbf{P} \cdot \mathbf{B}' + \mathbf{B} \cdot \mathbf{P}'$
Cross	% recombination
A ⁻ gal bio $ imes$ P ⁻ red ⁻	2.9
A gal bio $ imes$ P red int	0.01
A ⁻ gal bio $ imes$ P ⁻ red ⁻ xis ⁻	1.9
2. "Excision" recombination: P \cdot B' $ imes$ B	$\cdot \mathbf{P}' \to \mathbf{P} \cdot \mathbf{P}' + \mathbf{B} \cdot \mathbf{B}'$
Cross	% recombination
A^- bio $ imes$ P ⁻ gal red ⁻	10.0
A ⁻ bio $ imes$ P ⁻ gal red ⁻ int ⁻	0.05
A ⁻ bio $ imes$ P ⁻ gal red ⁻ xis ⁻	0.03

These data are abridged from Echols (1970). The host bacteria for the crosses were *rec*⁻. λ *bio* and λ *gal bio* are both deleted for *int. Red*⁻ phage are deficient for the general phage recombination system.

direction of Figure 4 requires *int* function but is independent of *xis* to the first approximation. On the other hand, recombination in the reverse, or excision, direction requires both *int* and *xis* function.

By what mechanism does *int* protein or *int* plus *xis* cut and join DNA molecules with the proper sequences? Undoubtedly, the answer awaits isolation and investigation of these proteins in vitro. One possibility is suggested by analogy with the structure of phage DNA cohesive ends. In this scheme, formulated in Figure 6, *int* protein would be a specific DNA endonuclease, which, recognizing the same short sequence of base pairs present in both $att\lambda$ of *E. coli* and

FIGURE 6 A hypothetical molecular mechanism for the insertion reaction. Between P and P' in λ DNA, and B and B' in bacterial DNA, the same base sequence, called the common sequence, is assumed to exist. The *int* protein is assumed to be an endonuclease specific for the common se-

quence and for the configuration $P \cdot P'/B \cdot B'$. An analogous series of reactions would be initiated by the *int* protein plus the *xis* protein, except that the starting configuration would have to be $P \cdot B'/B \cdot P'$.

in λ DNA, would cleave two phosphodiester bonds on opposite strands. (The common sequence would be represented by the dot in $P \cdot P'$ and $B \cdot B'$.) Cleavage would thus create an identical pair of cohesive ends in bacterial DNA and phage DNA. The ends could then spontaneously exchange pairing partners, and DNA ligase could re-form the missing phosphodiester bonds to complete the insertion of λ DNA into E. coli DNA. Further, the scheme would have it that the action of *int* enzyme is also controlled by base pairs flanking the common sequence. These base pairs, to the left and to the right of the common sequence, represented by P, P', B, and B', differentiate phage from bacterial DNA and prophage ends from both. The role of the xis protein would then be to change the specificity of int enzyme with respect to the flanking base pairs. Two testable deductions flow from this hypothesis. One is that there should be a common sequence of base pairs in λ and E. coli DNA at the site of insertion and excision exchange. Let us call the sequence C. The second deduction is that the recognition sequences P and P' flanking C must be short, so that both can be recognized simultaneously by one enzyme or enzyme complex.

Parkinson (1969) has isolated many deletion mutants of λ that remove segments of the attachment region. By electron microscopy of DNA-DNA hybrids formed between these mutants, he can place upper limits on the sizes of C, P, and P'. His current estimates are that P' must be less than 500 base pairs long and that P and C are each less than 50 base pairs. His experiments do not rule out the possibility that C is zero, that is, that the insertion-excision mechanism does not use cohesive ends. Further refinement will be necessary to settle this point.

General implications of the insertion-excision system

General genetic recombination resembles prophage insertion-excision in two respects. Both processes result in an exchange of parts of DNA molecules in such a way that no base pairs are gained or lost. Prophage insertion-excision, the general recombination system of eukaryotes, and the general recombination system in bacteria are all reciprocal. But resemblance seems to end there. In general recombination, two homologous DNA sequences recognize each other, most likely through base pairing (see, for example, Thomas, 1967), and general recombination enzymes are not sequence-specific. In insertion-excision, on the other hand, two specific, nonhomologous DNA sequences are recognized by sequence-specific proteins. Why, we might ask, do not temperate phage use their host's general recombination system for insertion-excision rather than synthesizing special proteins and providing special sequences? The answer is, I think, that, if they did so, lysogenic bacteria would be unstable because recombination would also excise the prophage. Bacterial episomes, which depend on homology and host recombination enzymes for their integration, are, in fact, less stable than a prophage in a single lysogenic bacterium. A prophage owes its stability, I would suggest, to the use of specific excision proteins, synthesis of which is repressed in the lysogenic state. Lysogenic bacteria are induced to produce phage by lifting this repression and releasing the synthesis of excision proteins along with other proteins needed for virus multiplication.

The ultimate effect of the two recognition systems described in this paper is a specific and stable translocation of genetic material. Similar molecular mechanisms might be used by higher cells during development to create new gene arrangements in somatic cells. For example, in antibody synthesis the association of a particular variable region with a constant region may be the consequence of gene translocation (Edelman, this volume). Control of hemoglobin synthesis offers another possible application. How is the production of a chains coordinated with γ chains in the fetus and with β chains in the adult animal? It is conceivable that the genes for the a and β chains, which are on separate chromosomes in germ cells, might be brought together by specific translocation in somatic cells at the appropriate time in development for their joint expression. Differentiating nerve cells may also exploit this possibility for stable and directed change. New methods for genetic analysis of somatic cells (Nabholz et al., 1969) may permit an experimental test of these possibilities.

Arrangement and Evolution of Eukaryotic Genes

G. M. EDELMAN and J. A. GALLY

IT IS A CLASSIC OBSERVATION that the architecture of eukaryotic chromosomes is quite unlike that of prokaryotes (see papers by C. A. Thomas and J. H. Taylor in this volume). The genetic information in the nuclear genome is packaged in a morphologically distinct set of organelles, the exact structure of which is still unknown. It appears that the eukaryotic chromosome is longitudinally arranged into structural subunits (Beermann, 1967), which may also serve as units of biosynthesis (Plaut et al., 1966; Huberman and Riggs, 1968), function, and evolution (Keyl, 1965). The proper functioning and replication of eukaryotic cells require additional structures, such as the mitotic apparatus, synaptonemal complexes, and nucleoli, none of which is found in bacteria.

Moreover, unlike bacteria, metazoan cells usually can be classified into two lines—germ cells and somatic cells. Although some single somatic cells of higher plants can be induced to give rise to complete, differentiated plants (Stewart et al., 1964), and nuclei of differentiated cells from the frog can provide the nuclear genetic material for regenerated animals (Gurdon and Woodland, 1968), irreversible alterations of somatic genomes may yet be found to play a

G. M. EDELMAN The Rockefeller University, New York, New York; J. A. GALLY Meharry Medical College, Nashville, Tennessee

major role in metazoan cell differentiation. Outside the laboratory, the genome of the somatic cell would never be called upon to reproduce a whole organism, and it might be free to undergo irreversible changes during differentiation. The many examples in which such changes are visible, such as polytenization, gene amplification (Pavan and da Cunha, 1969) and loss (Serra, 1968), breakage (McClintock, 1951), diminution (Beermann, 1966), or irreversible inactivation (Lyon, 1968) of chromosomes, all suggest the possibility that small, but significant, irreversible changes occur in the DNA from cell to cell. Recent studies suggesting the existence of "metabolic DNA" are in accord with such a suggestion (Pelc, 1968).

Rather than discuss the question of how gross chromosomal rearrangements or modifications might affect eukaryotic genetics, we shall review a number of specific phenomena that suggest that the arrangement and behavior of some of the genes in eukaryotes are fundamentally different from those in prokaryotes. The models proposed to account for these phenomena have two features in common: they all invoke a more-or-less directed or programed alteration in DNA sequences in the nuclear genome, and they presume the existence in the DNA of multiply repeated base sequences.

1. Antibodies. The experimental investigations on structural, genetic, and biosynthetic properties of immunoglobulins are discussed elsewhere (Edelman, this volume) and are summarized in a recent review (Edelman and Gall, 1969). The data suggest that each immunoglobulin polypeptide chain is coded for in the genome by two separate nucleotide sequences. Furthermore, these two sequences must fuse prior to the synthesis of mRNA for the chain. It has been suggested that this gene translocation also plays a role in the differentiation of the cell, committing it to the production of a single immunoglobulin molecule. In addition, there are good reasons for believing that the genes for the immunoglobulin polypeptide chains must diversify in some manner during ontogeny, requiring other sorts of programed alterations in somatic genes.

2. Transposable control elements. We refer here to the complex genetic systems in maize, described by McClintock (1965) and others (e.g., Peterson, 1961), and those in Drosophila, described by Green (1969). Although elements in these systems resemble certain aspects of genetic control in bacteria, e.g., diffusible repressors (Jacob and Monod, 1961) or an episome that can be translocated (Smith-Keary and Dawson, 1964), these analogies do not account for many of the details of the systems. McClintock's studies demonstrate that there are genetic elements in higher plants that can regulate gene expression. These elements do not remain localized in any one locus of the genome, however, but can be transposed from place to place on the chromosomes. Sometimes they control only those loci near which they are located, and sometimes they regulate many different loci distributed throughout the genome. These changes in position and inheritable "changes of state" (McClintock, 1951) imply molecular rearrangements in the genetic material that are sometimes made visible by localized chromosome breakage.

3. Paramutation. Brink (1964) has reported evidence that the genes controlling the rate of expression at certain loci in maize are inherently unstable and undergo changes during somatic-cell growth. As a result, the phenotype of the daughter cells changes toward a greater or lesser degree of phenotypic expression of the structural gene at the affected locus. The rate and direction of the change can be regulated by controlling the genetic background of the inherently unstable allele; in particular, the rate of this so-called paramutation is affected by the other alleles present at the paramutable locus. Other examples of similar phenomena are known in plants, and a seemingly analogous phenomenon has been observed in the bobbed loci of Drosophila (Ritossa, 1968). In both cases it has been presumed that the heritable changes involve alteration in the actual number of similar DNA sequences.

4. Gene amplification. Certain sites within eukaryotic chromosomes undergo differential replication. Pavan and da Cunha (1969), for example, have described "DNA puffs" in the dipteran species *Rhynchosciara angeli*. In certain differentiating cells of this species, the DNA at particular chromosomal loci replicates to such an extent that visibly enlarged amounts of DNA appear. The function of the DNA at these loci is not known. Other examples are provided by the evidence that the genes for rRNA replicate differentially during the oogenesis of a number of species that are distant from one another in the evolutionary tree (Gall, 1969). The production of the increased amounts of rDNA has been rationalized in terms of the large cytoplasm the egg nucleus must provide, as well as the lack of rRNA production during the early cleavage of the embryo (Brown and Gurdon, 1964).

Repeated DNA sequences

It is noteworthy that models proposed for all the genetic systems mentioned above postulated the existence in the genome of repeated DNA sequences before any direct evidence for these sequences was available. Multiple copies of genes for immunoglobulins were postulated in order to account for the enormous variety and specificity of antibodies that vertebrates can synthesize (Dreyer and Bennett, 1965). Because of the possibility of crossing over between paired, nonhomologous genes, instability is inherent in all repeated DNA sequences. Semi-stable genetic loci of this type readily allow quantitative variations and, therefore, multiple genes were invoked in models of both transposable control elements (McClintock, 1950) and paramutation (Smith-Keary and Dawson, 1964).

This potential instability led Thomas (1966) to suggest that the genome of prokaryotes would tend to evolve in order to eliminate or minimize the repetition of any long base sequences. His work, and that of others, provided evidence to support this hypothesis, for it was found, in a study of the rate of renaturation of DNA from bacteria and viruses, that repeated nucleotide sequences are rarely found in these genomes. In viruses, repetitive DNA appears at the end of recurrently redundant genomes, but apparently nowhere else. In bacteria, also, almost all the DNA sequences appear to be "unique," i.e., they occur only once per genome. A single bacterial chromosome can contain a number of genes coding for rRNA (Kohne, 1969), but these genes appear to be maintained by the requirement for large amounts of rRNA in the bacterial cell (Mueller and Bremer, 1968).

It has been suspected for several years, however, that such constraints on repetitive DNA sequences may not apply strictly to eukaryotes. Direct studies of the rate of renaturation of nuclear DNA (both somatic and germ-line) have indicated that repeated DNA sequences occur with high frequency (Martin and Hoyer, 1966; Britten and Kohne, 1965). Repetitious DNA has been detected in the genomes of all eukaryotes whose DNA has been studied by this method, including a few organisms from most of the major phyla of plants and animals (Britten and Kohne, 1968). The amount of repetitious DNA present is hardly negligible, amounting to about 40 per cent of the DNA in calf thymus, for example. Obviously, this implies that the rest of the DNA represents unique, i.e., unrepeated, genes. It now appears that the existence of easily detectable amounts of repetitious DNA is as characteristic of eukaryotes as is the nuclear membrane or the mitotic apparatus. In view of the possibility that repetitious DNA may confer characteristic genetic properties upon eukaryotes, the acquisition of the ability to maintain the repeated nucleotide sequences in a stable form may have marked a very important step in the evolution of all nucleated cells. Indeed, chromosomes themselves may have evolved mainly to allow multiple genes to exist and function in a stable fashion.

The use of a single term, such as "repetitious DNA," to refer to all examples of repeated nucleotide sequences in the genome may be misleading. It is probable, for example, that repeated DNA sequences include genes for ribosomal and transfer RNA, nucleotide sequences having other functions, such as those concerned with replication and recombination of chromosomes, and multiple, tandem-duplicated, structural genes for proteins.

That rRNA genes fall into the class of repetitious DNA has been demonstrated by DNA-RNA hybridization experiments, in which labeled rRNA was used as one of the hybridizing species. The number of rRNA genes has been estimated to range from 100 to 400 in a haploid set of chromosomes in species as varied as yeasts (Retel and Planta, (1968), Drosophila (Ritossa and Spiegelman, 1965), frogs (Wallace and Birnstiel, 1966), pea seedlings (Chipchase and Birnstiel, 1963), and man (Attardi et al., 1965). As in bacteria, a single rRNA gene per cell could not be transcribed at a rate sufficiently rapid to provide enough of this essential structural component of the protein-synthetic apparatus. This alone might account for the multiple copies found in the genome (Kohne, 1969). Similarly, the genes for tRNA (Ritossa et al., 1966) and 5S RNA (Brown and Weber, 1968) molecules appear to be repeated in the chromosomes, in some cases to a very high degree (27,000 5S RNA genes in germ-line and somatic cells of certain frogs [Brown and Weber, 1968]).

In addition to tRNA and rRNA, other RNA species of unknown function are also transcribed from the repetitious DNA. Because of the large size of eukaryotic genomes, RNA transcribed from a *unique* DNA sequence would not be expected to hybridize with cellular DNA at an easily detectable rate. Because it is known that much of the nonribosomal RNA in the cell does indeed hybridize rapidly with nuclear DNA, it has been concluded that some of the repetitious DNA is being transcribed (Britten and Kohne, 1968). It should be pointed out, however, that a portion of the repetitious DNA in eukaryotic genomes may never be transcribed into RNA. For example, Flamm et al. (1969) report that the extremely repetitious DNA of the mouse does not appear to hybridize with any RNA found in a number of different somatic tissues. This satellite DNA accounts for about 10 per cent of the mouse genome and appears to consist of roughly a million copies, each about 400 nucleotides long (Waring and Britten, 1966).

In contrast to ribosomal and tRNA genes, there is no evidence to suggest that the structural genes for the more commonly studied eukaryotic proteins, such as cytochrome c (Margoliash et al., 1969), are specified by many gene copies in the genome-although, in some cases, indirect arguments for multiple genes can be formulated, based on the observed rates of synthesis of these proteins (Jerne, 1967). The primary structures of a number of nonallelic proteins are quite similar, however, and it appears probable that the genes for their constituent polypeptide chains arose through gene duplication (presumably as a result of unequal crossing over), followed by evolutionary divergence. Examples of such proteins include the various hemoglobins (Ingram, 1963), the immunoglobulins (Edelman, this volume), and such functionally distinct proteins as lysozyme and lactalbumin (Hill et al., 1969). Obviously, such a process could not proceed if duplicated DNA sequences were rapidly eliminated from the gene pool; some mechanism must exist to prevent such rapid elimination. The homogeneity of the proteins isolated from homozygous animals, the kinds of polymorphism observed (for example, in human hemoglobins), and the nature of the evolutionary differences in the amino-acid sequences of homologous proteins from different animal species, all provide strong arguments for the existence of a single structural gene copy for most of the proteins so far studied. Experimental methods such as hybridization with purified messengers may, when they become available, permit a direct estimate of the number of genes involved.

At present, one can only speculate on the functions of much of the repeated DNA in eukaryotes. For example, repetitious DNA might contain binding sites for chromosomal proteins or chromosomal RNA, as suggested by the studies of Huang and Bonner (1965) on protein-linked chromosomal RNA. Chromosomal RNA has been reported to affect the specificity of histone-DNA interactions (Bekhor et al., 1969b; Huang and Huang, 1969) and appears to bind to repetitious DNA sequences (Bonner and Widholm, 1967). This possible function of repetitious DNA has been recently reviewed (Britten and Davidson, 1969). The peculiarities of this hybridization reaction, however, leave some doubt as to whether the usual linkage between complementary base-pairs of the nucleic acid strands is involved (Bekhor et al., 1969a).

A certain portion of the repetitious DNA may play a role

in determining how DNA fibers fold in the chromosome, either by Watson-Crick pairing or by serving as binding sites for proteins that stabilize metaphase chromosomes and the synaptonemal complex. The finding of Maio and Schildkraut (1969), that repetitious DNA is evenly distributed in the mouse chromosomes and is tightly bound to their structural components, is consistent with this hypothesis. As separated strands of repetitious DNA renature much more rapidly than strands of DNA of unique sequence, repetitious DNA may function to aid chromosomal recombination or to aid in the repair of chromosomal breakage. Either function would provide a ready explanation for the observed ability of broken ends of chromosomes to rejoin one another. Similarly, repeated DNA sequences might aid pairing during meiosis.

A fraction of repetitious DNA may not contain any genetic "information" at all but may have evolved to function merely as a space-filler in the genome. This possibility would at least provide an explanation for the great disparity between the large number of genes that can be encoded in the nuclear DNA and the much smaller number of genes that have been estimated to be present in the chromosomes. (This discrepancy is discussed at length by C. A. Thomas elsewhere in this volume.) There appears to be no great correlation between the structural complexity of an organism and the amount of DNA in its genome. A good correlation has been reported between the amount of DNA per nucleus and the nuclear volume, however (Commoner, 1964), and this correlation holds true both for a number of vertebrate species and for bacteria (DNA/cell volume). The large differences in the amount of DNA in closely related species (Keyl, 1965; Fox, 1969) are also consistent with the idea that the amount of genetic material present is controlled by some property other than information content. The controlling factor might be rather nonspecific and trivial, such as the maintenance of the nuclear viscosity. If so, the ease with which repetitious DNA can expand or contract in amount, by mechanisms that are discussed below, might make it an excellent "fill" material, inert and innocuous. This possible function for repetitious DNA would be most difficult to prove directly and, in any case, is esthetically displeasing.

Finally, some repetitious DNA may consist not of identical copies, but rather of a large number of *similar* genes capable of storing large amounts of genetic information. There may exist, in the antibody system, the nervous system, and other systems of like complexity, a requirement for a very large store of preadapted genetic information. Much of this information would function only at rare, critical times in the lifetime of the organism, and thus would remain inactive much of the time. As suggested by Zukerkandl and Pauling (1962), repetitious DNA might also represent a storehouse of evolving genes. Sheltered in these duplications, there might exist evolving variants of structural genes for important enzymes. This rather romantic view of the multiple-gene copies is difficult to reconcile, however, with certain fundamental theorems of population biology.

We can summarize these speculations about the genetic functions of repetitious DNA by concluding that, whatever they are, they are probably diverse. Regardless of the function of repetitious DNA, however, its very existence raises fundamental problems for evolutionary theory.

The evolution of repetitious DNA

The existence of repetitious DNA poses several new and difficult problems for classical Mendelian genetics and evolutionary theory. The key observations to be accounted for include:

1. The genomes of all investigated eukaryotic cells contain large numbers of DNA sequences which resemble one another far more than would be expected if they had evolved independently and by chance (Martin and Hoyer, 1966; Britten and Kohne, 1965). Similar sequences are not found in prokaryotic genomes (Thomas, 1966).

2. In any one species, these repeated DNA sequences can be divided into "families" of genes. In some families, the duplicated genes resemble one another very closely; in other families the members have diverged. All the families also differ in both number of members and length of the reiterated sequence (Britten and Kohne, 1965, 1968).

3. Denatured repetitious DNA strands from the nucleus of one species will renature more rapidly with one another than they will with the analogous strands from another species. Even closely related species can contain distinctively different repetitious DNA sequences (Martin and Hoyer, 1966; Britten and Kohne, 1966; Walker, 1968).

It is perhaps this third point that is most perplexing and, in fact, as we attempt to show, it suggests a new idea: in certain instances, all the members of the gene family change together, so that certain sets of closely related genes evolve to *different* sets of genes which are *also closely related*. For convenience, we call this process *coevolution of DNA sequences*.

Given the existence of multiple genes, how does natural selection operate at all? One might suppose that duplicated gene sequences would be buffered against rapid changes during evolution. If a certain gene is represented a great many times (100 or more) in the genome, any mutation in one of the copies could not greatly affect the selection pressures acting on a given individual, unless it led to the production of an actively deleterious gene product. For example, if a mutation occurs in *just one* rRNA gene, making the RNA transcribed from that gene unable to fold into a functional ribosome, no detectable effect on the viability of the animal would be expected. Frogs that lack half of their rRNA genes are known to be quite viable (Brown and Gurdon, 1964). The problem is even greater if all the genes in the family do not function simultaneously: what selection pressure could operate to maintain the constancy of an inert gene? Moreover, any rare "favorable" mutation that increases the efficiency of its gene product would be diluted in the cell with products of hundreds of its nonmutant sister genes. Therefore, it is difficult to see how natural selection could increase the gene frequency of these favorable mutants.

In trying to explain the evolutionary behavior of highly reiterated identical genes, one might assume that most single-base changes in the repetitious DNA represent truly "neutral" mutations, i.e., mutations that could confer no detectable selective advantage or disadvantage on the organisms. The possible fate of such neutral mutations is at present a matter of spirited controversy (King and Jukes, 1969). Depending on the viewpoint taken, one might expect that: (a) members of a family of like genes would gradually diverge from one another by the action of genetic drift acting on random neutral mutations (King and Jukes, 1969; Kimura, 1968), or (b) a family of a large number of like genes would remain constant from species to species throughout evolutionary time, because neutral mutations can never attain an appreciable gene frequency in a large, randomly breeding population (Simpson, 1964).

In fact, the data are not in accord with either expectation. The DNA representing the repeated sequences apparently can evolve, for it differs considerably from species to species (Martin and Hoyer, 1966; Zuckerkandl and Pauling, 1962; Britten and Kohne, 1966). This evolution is not necessarily accompanied by a general divergence of the members of each duplicated gene family within a species, however, and the genes thus can coevolve. What is the evidence that such a process occurs? The most clear-cut example is provided by the rRNA genes. We have already reviewed the evidence that these genes are multiply represented in nuclear chromosomes. It has also been shown that these genes do differ from species to species (Pinder et al., 1969). Although some hybridization experiments suggest that rRNA genes in a single nucleus are not all identical (Moore and McCarthy, 1968), they appear to be more closely homologous to one another than to rRNA genes of other species. The exact degree of similarity of the base sequences of rRNA among different species has not yet been determined, but human and mouse 28S rRNA can be separated on the basis of physicochemical properties (Eliceiri and Green, 1969), suggesting that none of the rRNA genes in one species is identical to any in the other species.

So far, it has not been shown that the genes for the 5S RNA or transfer RNA do, in fact, differ from species to species within eukaryotes. If they do differ, they, too, must coevolve. The highly reiterated satellite DNA sequences isolated from any one species are also more closely related to one another than they are to similar fractions from other species (Walker, 1968). In the absence of knowledge about their function, however, the assumption that these fractions are evolutionarily homologous appears less compelling. The data on immunoglobulin sequences and genetics (Edelman, this volume) may also provide an example for multiple-gene coevolution.

Possible mechanisms to account for coevolution of DNA sequences

What mechanisms account for coevolution of multiple genes? Perhaps the simplest answer is to rely on the "invisible hand" of natural selection, and to leave it at that. If, for example, there is a single optimal rRNA sequence for mouse ribosomes, all the gene copies might have undergone exactly parallel evolution to the same end-product by random-point mutations acted upon by selective forces. We believe this to be most unlikely. It appears that a very specific mechanism is necessary, and we briefly describe some of those that have been proposed.

1. Reiteration or incorporation of multiple copies. Britten and Kohne have suggested that coevolution can be accounted for by genetic "bursts" (Britten and Kohne, 1965, 1968), i.e., single-gene copies undergo a process of reiterative replication in the germ-line of certain individuals (Figure 1A). The gene frequencies of the duplicated genes increase, presumably because they confer some selective advantage and, therefore, eventually become fixed in the population. Following such "saltatory evolution," which must occur fairly frequently to account for the observed differences between closely related species, the initially identical genes gradually diverge from one another by random drift, becoming more and more heterogeneous. Presumably a compensatory gene loss also occurs frequently to make space for the genes introduced by the "bursts," because the total genome size does not increase proportionately. According to this picture, each gene family would arise from a different initial "burst." The age of a family would be correlated with the amount of heterogeneity of its gene sequences, and, therefore, the newest families would consist of almost identical genes.

The molecular mechanism underlying the "burst" event has not been specified, but presumably it might resemble that required for gene amplification of oocyte rRNA genes (Gall, 1969) or DNA "puffs" (Pavan and da Cunha, 1969). The even distribution of the family of highly repetitive DNA throughout the karyotype of mice argues against this proposal, unless the genes can somehow translocate swiftly through the genome soon after being generated (Bekhor et al., 1969a; 1969b).

Another mechanism suggested by Britten and Kohne (1966), viz., incorporation of multiple copies of lysogenic viral genomes, might account for the even distribution. The

GENE REITERATION

FIGURE 1 A. One possible molecular mechanism for gene reiteration. (1) DNA sequences within vertical bars are similar to one another. For clarity the double-helix is drawn unwound in these sequences only. The process involves pairing of like sequences (2), nucleolytic attack, hybrid-DNA formation, and repair synthesis of the DNA (3). These steps lead to a larger family of like genes (4). (Other mechanisms for reiteration are possible; see Thomas, this volume; and Pavan and da Cunha, 1969.) B. (1) Recombination between paired, tandem, similar but non-homologous DNA sequences in different chromatids increases the number of members of one gene family and decreases the number in the paired chromatid. (2) This process, if continued, can lead to progressively larger gene families. (3) Pairing and recombination between two members of a gene family on a single chromatid would lead to formation of an episome which might be able to integrate elsewhere in the genome(4). actual mechanism would resemble that illustrated in Figure 1, B3. The recent demonstration that many copies of the genomes of human oncogenic viruses can become incorporated into the nucleus of a single transformed cell provides a model for this mechanism (Dulbecco, 1968). The small size of the repeated base sequences in the highly repetitious DNA of mouse (Waring and Britten, 1966), however, would not appear to be able to code for a complete viral genome.

The other mechanisms that have been proposed to account for gene coevolution all involve the ability of repeated DNA base sequences to mispair, i.e., to join in Watson-Crick base-pairing with nonhomologous members of the family located on the same or different chromosomes. Genetic recombination events that take place in these mispaired regions might allow base-sequence information to be transmitted from sequence to sequence along a tandemly duplicated gene family, thus aiding in their coevolution. A number of different mechanisms could account for this phenomenon, depending on the exact nature of the recombination and conversion steps postulated. Some specific examples are discussed below.

2. Reciprocal, unequal crossing over. The mispaired regions might undergo a breakage and reunion process in which both strands of the DNA exchange partners (Figure 1B). If the mispaired genes are on different chromosomes, or on different chromatids of replicated chromosomes, an increase in the number of tandem-repeated genes in one chromosome and an equivalent decrease in the other would result. If the mispaired genes were on the same chromosome, a loop of tandem genes might be deleted. This loop might be lost from the nucleus, or it might be re-incorporated elsewhere in the genome in a lysogenic fashion (Figure 1B).

The potentialities inherent in unequal crossing over have long been known. It is the most commonly accepted hypothesis to account for the incorporation of new structural genes into the genome, and the interesting instabilities to which it might give rise have been investigated by a number of workers (Lewis, 1967). Paramutation phenomena (Brink, 1964) have been explained in this way and a similar mechanism may operate in the bobbed mutants of Drosophila (Ritossa, 1968). Bobbed mutants apparently arise as a result of deletions of a large number of linked rRNA genes. Some of these deletions are in turn unusually unstable, and revert to normal, a change that is accompanied by an increase in the number of detectable rRNA genes in the genome. It has been suggested that these genes are held in a dynamic equilibrium in the population. The number of genes can either increase or decrease as a result of unequal crossing over, and natural selection operates to maintain the gene fraction found in pooled individuals (Ritossa et al., 1966). In a dynamic system of this sort, an allele arising from a point mutation in an rRNA gene which confers selective

advantage to an organism can increase in gene frequency, both in the population *and* in the tandem set of genes in one organism. This might well account for the coevolution of genes in a species.

3. Master and slave genes. As a result of a careful investigation of the lampbrush chromosomes of amphibian oocytes, Callan (1967) concluded that each of the lateral loops represented a functional unit of the chromosome, and that each loop might produce only a single gene product. This is discussed at length in Thomas's paper in this volume. Because these loops are far longer than would be expected for a single structural cistron, Callan suggested that they consist of a series of tandem-repeated identical genes (Figure 2A). To account for the coevolution of the gene sequences implied by such a structural arrangement, he suggested that one member of each sequence has some distinctive property (perhaps its position in the series) which would cause it to act as a "master" gene. The other members of the duplicated set are referred to as "slave" genes. At some time during the growth of the germ cells of each individual, the nucleotide strands of the DNA sequences coding for the slave genes would unwind in order to allow these strands to form double helixes with the complementary strands of the master gene. If the sequences of the master and the slave were identical, the slave would dissociate and renature with its original strand. If the slave gene had incorporated a point mutation prior to the last comparison with the master gene, a distortion would be created in the master-slave hybrid that could be enzymatically corrected by changing the slave strand to complement the master strand. Mutations in the master gene would be incorporated in each of the slave copies. As a result of these hypothetical steps, all the repeated genes would evolve in exactly the same way and at the same rate as the single master gene.

Detailed mechanisms for the master-slave comparison process have been proposed by Whitehouse (1967a) and Thomas (this volume), and variant schemes have been advanced to account both for antibody variability (Whitehouse, 1967b) and for gene instability in plants (Fincham, 1967). A possible variant of the master-slave scheme is to propose that all slave genes are lost by intrachromosomal recombination at some stage in germ-cell growth and replaced by gene amplification of the single master gene remaining in the chromosome (Markert, 1968). No evidence for any *general* gene amplification in germ cells has been reported, however, despite a great deal of work on DNA content and biosynthesis in the nuclei of these cells.

In contrast to the other mechanisms discussed here, the master-slave mechanism predicts that all members of a gene family would remain identical as long as they remain under a single master. Accordingly, this model would be the only one consistent with the hypothesis (Thomas, this volume) that structural genes for the commonly studied proteins

FIGURE 2 A. The master gene (filled circles) pairs with each slave gene (open circles). Any differences in the nucleotide sequences of the slave genes (indicated by crosses) are excised and repaired, so that each slave gene in a corrected gene family is identical to the master gene. B. (1) A family of like genes can accumulate point mutations (closed circles and triangles), causing the tandem genes to be nonidentical.

crease the frequency of some of these mutant sequences and decrease or eliminate others. (For details, see Edelman, page 885.) (3) A point mutation that confers selective advantage to the species might spread to all members of the gene family by means of conversion and natural selection.

have a high multiplicity. The gene duplications postulated to account for the evolution of various hemoglobin polypeptide chains, for example, would then require the duplication of whole sets of both master and slave genes, followed by divergence of the master gene. The master-slave mechanism would not easily account, however, for partial gene duplications or for the unequal crossing over which has been postulated to give rise to the genes for Lepore hemoglobin (Baglioni, 1963) and variant gamma chains of human immunoglobulins (Kunkel et al., 1969).

4. "Democratic" gene conversion. We have suggested that the observed sequences of variable regions of immunoglobulin chains might arise through unequal intrachromosomal crossing over among tandem duplicated genes (Edelman and Gally, 1967; Edelman, this volume). Such recombination might be either reciprocal or, more likely, nonreciprocal. Recent experiments on recombination suggest that the recombining DNA molecules join by forming hybrid helixes containing complementary strands from different origins (Meselson, 1967). Enzymatic steps after the formation of such hybrid duplexes are assumed to excise and repair stretches of the molecular hybrid. The result would be nonreciprocal recombination or conversion. We have found several enzymes (Lindahl and Edelman, 1968; Lindahl et al., 1969a, 1969b) in the somatic cells of mammals that might play roles in such a mechanism. Gene conversion has been observed in many eukaryotic (Holliday, 1964; Whitehouse and Hastings, 1965) and some prokaryotic (Sermonti and Carere, 1968) genomes, and it has been suggested that conversion plays a major role in evolution (Fogel and Mortimer, 1969).

One of us (Gally) has proposed that democratic gene conversion (Figure 2B) might provide an additional mechanism to account for the coevolution of repeated genes. It is assumed that mispairing and nonreciprocal recombination take place frequently between the members of a family of like but nonidentical genes. Each member of a family would repeatedly compare itself with other members by hybrid DNA formation, and mismatched base-pairs in the hybrid DNA would tend to be eliminated by enzymatic excision and repair processes. In this mechanism, neither DNA strand would be treated preferentially, and a new point mutation would be as likely to be copied as to be eliminated. Thus, a selectively advantageous mutation in only one member of a large family has the potential of distributing itself throughout the family much more rapidly than it could by independent mutation and selection.

Because the rate of appearance of point mutants is proportional to the length of the nucleotide sequence in which they can occur, we might think of families of democratically converting, tandem genes as mutation "nets" capable of trapping favorable mutations, which can then spread laterally through the family. Disadvantageous mutants would be rapidly eliminated.

The rate of coevolution would depend on the phenotypic function of the gene product and on the rate of the conversion process. Depending on the nature of the selective forces acting on the final gene product, members of a family of like genes may be similar or they may diverge with a high degree of heterogeneity. Democratic gene conversion would not allow for the simultaneous alteration of the homologous base-pairs in *all* members of the family, as would occur in the master-slave gene conversion model. Therefore, we would not expect to find polymorphism among democratically converting genes.

If a gene family were split up by a translocation event so that members of one part of the family could no longer recombine with the rest, the two parts of the original family would no longer evolve together. If gene conversion accounts for the evolutionary behavior of rRNA genes, for example, it would predict that the rRNA genes in one autosome of a haploid set would resemble one another more closely than those on a nonhomologous chromosome. A gene family on one chromosome which is prevented from crossing over with its homologue in a diploid set (e.g., by chromosomal inversion) would likewise not be able to coevolve with the corresponding genes on the homologous chromosome. This would give rise to *apparent* polymorphism of multiple genes in a population, but such "pseudopolymorphism," *would not resemble* that described for structural genes. For example, the gene family would not differ from its "polymorphic" alternative by a single nucleotide at a certain position of each gene. Instead, the differences would resemble those found in the genes for the amino terminal position of the immunoglobulin heavy chains of rabbits of different allotypes (Koshland, 1967; Wilkinson, 1969).

If gene conversion occurred, many of the questions that have been asked concerning the frequencies and changes of frequencies of genes within a population could be asked about gene frequencies within an organism. Many of the concepts developed to account for the evolution of sexually recombining populations, e.g., the prevalence of heterosis, might be expected to apply to the populations of genes found within repeated gene families in a single chromosome.

The mechanisms to account for the coevolution of multiple genes discussed above are not exhaustive, and none of them may be correct. They do, however, show how unstable, dynamic systems, which would greatly increase evolutionary possibilities, might be generated by means of known biochemical rearrangements and transformations of DNA. These systems could behave as "genetic algorithms," i.e., by establishing a relatively short basic nucleotide sequence and a number of rules to govern its rearrangement, vast new arrays of information may be created upon which natural selection might be able to act. At present, the task is to provide experimental evidence for or against any of the hypothetical models that have been presented to account for the evolution of multiple genes.

The Theory of the Master Gene

C. A. THOMAS, JR.

THE THEORY of the master gene was first advanced in a remarkable paper by Callan and Lloyd that appeared in the Philosophical Transactions of the Royal Society of London in 1960. This theory was based on the morphological study, by optical phase-contrast microscopy, of the lampbrush chromosomes from the oocytes of newts. The studies of lampbrush chromosomes by Callan, Gall, Macgregor, and others that appeared during the 1950s combine to form an important series of observations. The theory itself must be considered a triumph of reason. It is outrageous in every respect. Its only direct support, even to this day, is based on morphological considerations. When first proposed, the nature of the chromatid was not known, although the Taylor, Woods, and Hughes paper (1957) had appeared, touching off the debate between the "uninemists" and the "polynemists" that persists to this day. Callan supposed a chromatid to be fundamentally a duplex DNA molecule, a view that must now be considered essentially correct. To account for his observations, Callan supposed that genes were often found in multiple representation-"serially repeated," perhaps 100 to 10,000 times along the chromatid or DNA duplex. This model challenged the conventional wisdom of two generations of Mendelian geneticists, who have supplied overwhelming evidence that alleles are inherited in an all-or-nothing manner. To answer this profound objection, Callan supposed that the nucleotide sequence of each of the repeated genes is brought into accord with that of a "master copy" by some unspecified mechanism. Thus, only mutations in the master copy would be recovered; those occurring in other copies would be brought into accord with the master copy-that is, would revert to wild type.

In view of the unfamiliar character of the material (the oocytes of newts) and the apparent incongruity of this theory with both Mendelian and molecular genetics, together with the *ad hoc* character of the master gene and its role in specifying the thousands of identical serial copies, it is not surprising that this theory was greeted with skepticism. Now, however, converging lines of evidence lead one seriously to consider the idea. If correct, the theory of the master gene will directly affect every aspect of our present understanding of biology. Therefore, it is worthwhile to

C. A. THOMAS, JR. Department of Biological Chemistry, Harvard Medical School, Boston, Massachusetts study the lines of evidence that support the theory and then to discuss some of its predictions.

The theory

The exposition that follows is based on the ideas found in the 1960 paper and on their extensions (Callan, 1967). Substantial modifications have, however, been made and new vocabulary has been added, so Callan should not be held totally responsible for what follows. The scheme is presented in starkest form for clarity, even though the resulting outline is not adequate to represent the variety and variation seen in nature.

The eukaryotic chromatid (the chromosome after mitosis, but before a round of DNA synthesis) is fundamentally a single DNA duplex in which the entire genetic text is represented in nucleotide sequence only once. Most or all genes (or operons) specifying RNA or protein molecules are represented not once but 100 to 10,000 times. This is accomplished by the serial repetition of each gene type an exact number of times. On passing along the linear DNA molecule from gene to gene in a given series (or family), a miniature observer of nucleotide sequence would be unable to tell that he was not repeatedly moving around the same circular DNA molecule containing the single gene (Figure 1). The sequence of each serially repeated gene is identical to every other serially repeated gene in the same family.

A special member of each gene family is called the *master* gene; all other members are called slaves. (In Figure 1, the master gene is depicted as the first member of the series.) In the germ line of cells, and probably in somatic cells as well, the master gene specifies the sequence of every slave in the family. It does so by a process called rectification. Whether rectification is accomplished by repair synthesis, replacement, or replication need not be specified at this moment. Rectification must occur about as frequently as cell division, although it could be more frequent. Because of rectification, only mutational alterations in the master gene are ever detected. Both masters and slaves are transmitted through the germ line (to sperm and egg) without an increase or decrease in their number. The "one gene-one protein theory" is to be modified to read "one gene family-oneprotein type." Because the sequence of all slaves is identical, those sequences controlling the rate of transcription of RNA (the promoter and operator regions) are identical. Thus, it is to be expected that entire families of genes are

FIGURE 1 The eukaryotic chromosome: masters and slaves. The chromatid is pictured to be a single DNA molecule containing gene families, each made up of a defined (large) number of identical genes. One gene, called the *master*, is

turned on or off together. They would be expected to function as a unit. In this case, the family size would determine the abundance of the messenger RNA it specifies. If repressor molecules or RNA polymerase were limiting, a graded response that is controlled by their concentration could be achieved.

Gene families are considered to be found only in the "higher forms." In the lower forms, such as bacteria and viruses, genes are usually represented only once. Every gene is a "master gene." A general comparison of the two basic biological forms is revealing (Table I). As this comparison suggests, there is a profound difference between the miniature organisms and the comparatively monstrous cells that make up the so-called higher forms. The major differences are the *size* of the cell and the way it manages its hereditary apparatus.

	Table	I		
A Comparison	of Lower	and	Higher	Forms

Lower Forms	Higher Forms			
(Prokaryotes)	(Eukaryotes)			
Low DNA content	Very high DNA content			
(small cell size and weight)	(large cell size and weight)			
No organized chromosomes	Organized chromosomes			
(chromonemal)	(chromosomal)			
No basic proteins	DNA united with basic proteins			
No nuclear membrane	Nuclear membrane			
Little differentiation	Elaborate differentiation			
All cells master cells	Germ line and somatic cells			
(aging unknown)	(somatic cells age)			
All genes master genes	Most genes in large "families" of identical members			

depicted as the first of a series of identical slaves. The genes of one family can differ in sequence from those in another, although they may be related sequences.

The morphology and function of lampbrush chromosomes

Although this evidence is, in many ways, the most difficult to recount, the lampbrush chromosome played the significant role historically. In order to understand the arguments of Callan, one must review what is known about these wonderful structures.

Lampbrush chromosomes are found in the oocytes (and in some species, the spermatocytes) of almost every species studied—from arrow worms to humans (Baker and Franchi, 1967). They were first encountered by Flemming and studied by Rückert, who gave them their name before the turn of the century. With the advent of phase optics, unfixed preparations could be studied. Other innovations by Gall, Callan, and others have made it possible to study the morphology of these chromosomes in considerable detail. Miller and Beatty (1969a, 1969b) have recently made a significant advance in the preparation of lampbrush chromosomes for electron microscopy that allows them to be studied at the molecular level.

Generally speaking, oocytes are arrested in the process of meiosis. The chromosomes are held at the *diplotene* stage, which means that all chromatids are double, as they were replicated just prior to meiotic prophase. The homologous two-stranded chromosomes have paired with each other to form the four-stranded complex (*pachytene*), and have begun to separate and are visibly double, thereby revealing any chiasmata that may have taken place (*diplotene*). In newts, for example, they may wait in this condition for up to two years; in humans for up to 40 years or more. During this time, the oocyte accumulates yolk, ribosomes, and other ingredients for the egg. Just prior to ovulation, the oocyte engages in two divisions to produce the egg. This process reduces the chromosomal DNA from a value of 4C to 1C (C refers to the haploid complement of DNA).

The chromosomes in the arrested diplotene stage are not compacted; rather, they are expanded and elongated to lengths ranging from 200 to 800μ in *Triturus*. Each of the

two homologous chromosomes that form the so-called meiotic *bivalent* appear to be composed of rows of dense bodies called *chromomeres*. Two lateral loops project from many, but not all, chromomeres (Figure 2). The two loops from a given chromomere are invariably identical in length and appearance. We now know, mainly from electron micrographs and nuclease sensitivity, that the axis of these loop (and chromomere) itself—a local phenotypic expression of local DNA nucleotide sequence (Figure 4). This idea is given dramatic support by the electron micrographs of Oscar Miller that show the DNA molecule in the act of being transcribed into long RNA chains: An example is shown in Figure 5 (page 978). Autoradiographs reveal that radiolabeled ribonucleotides are incorporated in all regions of the

FIGURE 2 The morphology of lampbrush chromosomes. The chromatid (DNA duplex) replicates to become "double"; it then unites with its homologue, crosses over, begins to separate, and is arrested. Each chromosome is still double,

loops is a single DNA duplex: the pair of loop axes are the two chromatids produced by the pre-meiotic replication event (Figure 3). The bulk of the loop material is RNA and protein. All loops that can be studied carefully show a thin and a thick end. The thin ends always point either toward or away from the centromere, depending on the loop in question.

The appearance of many of the larger loops is specific to the chromosome and the subspecies or race. Callan's work demonstrates conclusively that the morphology of these loops is genetically specified, and leaves little doubt that the DNA that specifies the loop morphology resides in the

and each loop contains a DNA duplex as its axis. Tension splits the chromomere laterally. In some species, longitudinal chromomere splitting is seen to take place naturally.

loop. Certain unusual loops, however, such as the giant loop of chromosome XII of *Triturus cristatus*, seem to synthesize RNA in a special location near the pointed end of the loop (Gall and Callan, 1962). Thus, there is now direct evidence that the loops are macroscopic manifestations of underlying genes.

Many loops appear to slough off particulate matter into the nuclear sap. Callan noticed that these particles often were shed from the thick end of the loop *and* from intermediate positions as well. Moreover, sometimes a given loop is found that is not fully extended from the chromomere, yet it, too, sheds the same kind of particulate matter.

FIGURE 3 Phase contrast photograph of a lampbrush chromosome. (Courtesy of J. Gall.)

976 RECOGNITION AND CONTROL AT THE MOLECULAR LEVEL

FIGURE 4 Schematic diagram of how the DNA in the loops of a lampbrush chromosome is thought to be "expressed" transcribed. It is not yet clear whether the RNA is translated

If we assume that particles that detach from a loop are "fully fashioned" gene products, the question presents itself: How can different regions of the same loop produce what appears to be the same material? Weighing carefully some alternative explanations, Callan (Callan and Lloyd, 1960) advanced the most likely interpretation: that there is "no diversity of genetic information within the loop"—that "the information carried by a particular region of the chromosome may be serially repeated along the loop axis."

In order to account for the asymmetry of the loops, Callan supposed that the loop axis moves—being continuously spun out from one part of the chromomere and reeled into the other. If, indeed, the loop axis moves, as seems to be the case in the giant loops of chromosome XII, the idea of repeating genes provides an easy explanation for the fact that the loops have a more or less constant morphology, irrespective of the age of the oocyte, which, as mentioned above, can extend to years! The loop appearance remains the same, because each new gene that is spun into the loop from the chromomere is identical with the others that preceded it.

It is not certain if all the elements of Callan's argument will be supported by future work. In particular, the extent to which protein synthesis occurs on the loops is not known. It could be possible that proteins made in the cytoplasm associate with loop material (RNA) to give it a characteristic appearance. Callan's conclusion could still apply, irrespective of how this important question is resolved. into protein as a general rule, although some protein synthesis is thought to occur in the oocyte nucleus.

Mutation and recombination

MUTATION RATE Only mutational alterations affecting the master gene will be observed, because those taking place in the slave genes will be rectified by an unaltered master. Thus, we would expect the mutation rate per gene to be much smaller in eukaryotes than in prokaryotes, in which every gene acts independently. Such proves to be the case, as shown in Table II. Here we see that the spontaneous, forward mutation rate, calculated per base pair per replication, for two eukaryotes (*Neurospora* and *Drosophila*) is about 1000 times lower than the rate seen in bacteriophage, which accords with expectation. Unfortunately, this evidence is

TABLE II Spontaneous Forward-Mutation Rate in Prokaryotes and Eukaryotes Per Nucleotide Pair, Per Replication

phage (λ , T ₄)	$1.7 - 2.4 \times 10^{-8}$
E. coli, S. typhimurium	2×10^{-10}
Neurospora crassa	0.7×10^{-11}
Drosophila melanogaster	7×10^{-11}

(From Drake, 1969.)

FIGURE 5 Electron micrograph of lampbrush chromosome loop. DNA duplex is the traverse thread; long RNA chains

extend from it. The numbers correspond to DNA measurements in arbitrary units. (Courtesy of O. L. Miller, Jr.)

not conclusive. Not only is the estimation of forward mutation rate subject to considerable uncertainty (Drake, 1969), but the known effects of antimutagenic DNA polymerase, and the possibilities of excision and repair of mutational heterozygotes, may affect the frequency of observed mutants to unknown extents. Indeed, the observed mutation rate of lambda replicating as a prophage is 20 to 100 times lower than when replicating during a cycle of vegetative growth. RECOMBINATION The concept that the chromosome is constructed of gene families leads to an unusual prediction regarding intergenic and intragenic recombination. As illustrated in Figure 6A, a recombination event among slave genes is effective in recombining gene families, but the process of rectification quickly eliminates recombinant slaves. On the other hand, a recombination event *within* a master gene leads to recombinant slaves as well as recombinant gene families (Figure 6B). Callan supposed that re-

FIGURE 6 A. Recombination between two master genes. B. Recombination within a single master gene.

combination is totally restricted to the master genes, because chiasmata are never seen in the lateral loops of the lampbrush chromosomes.

In phage and bacteria (in which every gene is a master), it is generally agreed that there is no discontinuity in the genetic map on passing from one gene to another. Intragenic and intergenic recombination proceeds at roughly the same rate (Figure 7A). The minimum intergenic recombination frequency can be less than the maximum intragenic recombination frequency. On the other hand, the situation is not equivalent in eukaryotes, as is diagramed in Figure 7B. genic recombination values could mean simply that intervening genes have not yet been recognized by mutations. Although these objections cannot be ruled out completely, I think it is very unlikely that the objections are valid. Thus, we find a second prediction of The Theory fulfilled: recombination between genes occurs more frequently than recombination within genes. But there is more.

Chromosomal rearrangements in Drosophila Such rearrangements (deletions, inversions, translocations) generally do not damage the genes at the point of refusion, although in some cases they do. In phage and *E. coli*, deletions

FIGURE 7 Recombination between and within genes. A. In prokaryotes. B. In eukaryotes (Drosophila).

Among the most closely spaced independent genes in *Drosophila*, the intergenic recombination values are about 10 times the *maximum* intragenic recombination values. This is illustrated in Table III, which contains information adapted from Pontecorvo's (1958) book. Evidence against this point is supplied by Chovnick's study of the *rosy* locus (1966). The *White-Notch* region, however, displays about 100 times more recombination than can be accounted for by the three genes it is known to contain (E. B. Lewis, personal communication, 1969).

Now, the molecular geneticist is quick to point out that the number of mutants available to the *Drosophila* geneticist may not be sufficient to mark truly the maximum intragenic distances that exist. Furthermore, large minimum internearly always damage the gene at the terminus of the deletion. In microorganisms, this effect is so predictable that it is the standard method for mapping the location of unknown markers. Why is it that chromosomal rearrangements can be made with relative impunity in higher organisms? One explanation could be that the inert material between genes recombines to form the rearranged chromosome. Another could be that unusual rejoining generally takes place among slave genes. On the next round of rectification, the full family of slaves is reconstituted, and the original slave family now finds itself neighbors to a new family of genes, with both families functional.

The Number of Nucleotide Pairs Per Gene Finally, we come to the amount of recombination in relation to DNA

TABLE III
Recombination Between and Within Genes

	Minimu Between	m R % n Genes	Maxi R % V Ger	aximum % Within Genes Ratio	
Drosophila 280 map units	w-rst sp-bl ey-ci	0.2, 0.5 0 3 0.2	w(4) bx(5) lz(3)	.056 .03 .14	
range	0.2 -	- 0.5	0.03 -	14	1.4 - 16
Aspergillus	y-ad16 ad15-paba	0.05 al 0.5	bi(3) ad8(6)	0.1 0.18	
range	0.05 -	- 0.5	0.1 -	0.18	0.28 - 5.0
T4	r11(A)-r11(B)	04(?)	r11(A) 4.3	.01

Conclusion: It appears that the minimum recombination that occurs between (presumably) neighboring genes in *Drosophila* is on the order of 10 times the maximum observed within a gene. This is contrasted with situation in T4, in which this ratio can be as small as 0.01. (Adapted from Pontecorvo, 1958.)

content. The total length of the genetic map is equal (after dividing by 100) to the average number of recombination events that have occurred per genome. If it be assumed that recombination events take place with equal probability in all intervals (which is wrong), and that the frequency of recombinants depends only on the length of the interval between the markers (which is also wrong), it is possible to calculate the total number of genes. This calculation is made in Table IV for T4, Drosophila, and Aspergillus from data assembled in Pontecorvo's (1958) book, somewhat revised. Here we see that T4 has about 100 to 200 genes, which is a reasonable value. About 80 have so far been identified (Sober, 1968). When compared with the number of nucleotide pairs in the molecule, one calculates about 1000 nucleotide pairs per gene. A gene of this length could specify a protein of 330 amino acids, or about 36,000 molecular weight. When we come to Drosophila, however, the estimated number of genes is only 10 times larger, yet the DNA content is 1000 times larger. The number of nucleotide pairs per gene calculates to 200,000, or 20 times larger than makes structural sense.

Now, there are many ways to explain away these results. The estimation of the number of genes is naive and ignores known effects that could make great differences. The increased DNA per gene could result from the possible polynemic nature of *Drosophila* chromatids or from the presence of nonfunctional "spacer DNA" between genes. All this may be true, but it is equally true that these facts are in exact accord with the idea that the genes in *Drosophila* (and all higher forms) are represented by *gene families*.

The Role of Histones The mechanism of genetic recombination between DNA molecules is just now becoming susceptible to mutational and biochemical study in phage. Ultimately, the recombination event must involve the annealing of complementary polynucleotide chains to form a duplex DNA molecule. No other known process has the specificity equal to the feat of producing recombinant molecules that (in general) have neither gained nor lost a single nucleotide. If this is assumed, the repetitive nature of a series of slave genes would provide multiple opportunities for crossover events, which would be between identical sequences, yet not homologous from the point of view of the whole chromosome. Such aberrant crossovers are depicted in Figure 8. This process, if allowed to happen, would lead to recombinants of unequal family size.

A more severe event is shown in Figure 9. Internal recombinations made possible by the repeating sequences lead to circular molecules (circles of slaves) and a reduction in family size. These events would have disastrous consequences and must be prevented. I suppose that this role is played by histones—the ever-present escort of all eukaryotic DNAs. Histones seem to complex with DNA and never irreversibly dissociate from it, following the polynucleotide chains through many cycles of replication and mitosis (Hancock, 1969). This view, if provisionally accepted, provides an explanation for the mysterious, superhelical DNA mole-

This calculation must be taken in a qualitative sense only. An important issue, namely, high negative interference, has been ignored. However, when this is properly taken into consideration (Stahl et al., 1964), one comes to the same number of genes per T4 chromosome.						
Species	Total Map	1 Gene	Calculated Total No. of Genes	Total NTP	NTP/Gene	
T4 Drosophila	400 280	2-4% 0.2-0.3%	100–200 1000	1.8×10^{5} 2×10^{8}	1000 200,000	
Aspergillus	660	0.5%	1320	4×10^{7}	30,000	

TABLE IV DNA Content Per Gene

Calculated from length of the genetic map, the map length of a gene, and the amount of DNA per haploid nucleus.

RECOMBINANTS OF UNEQUAL FAMILY SIZE

FIGURE 8 Possible unequal crossing over made possible by tandem duplications. This kind of crossing over produces recombinants of unequal family size.

INTERNAL RECOMBINATION DELETES THE SLAVES

RECOMBINANT OF REDUCED FAMILY SIZE

FIGURE 9 Internal recombination deletes the slaves. This process, if allowed to proceed, could delete all but a single gene.

cules of unusually short contour length, discovered by Radloff, Bauer, and Vinograd (1967) in *HeLa* cells. They could be "circles of slaves" that result from the recombination of tandemly-repeated genes that are imperfectly protected by histone.

These suggestions are supported by the known facts in $E. \ coli$. Here the DNA is *not protected* by histones. Known tandem duplications are rare. When they do occur, they suffer from a high degree of instability. They tend spontaneously to produce mutants that contain only a single copy of the gene. Such is the case with su_{III} genes (suppressors) that produce tyrosine tRNAs. In the su_{III}^+ strains, the anti-

codon of one of two tandemly-located tyrosine tRNA genes is altered from GUA to CUA, which presumably allows tyrosine to be inserted for the amber codon UAG. The important feature of this situation for the present argument is: (1) two copies of the tRNA gene reside in tandem in the *coli* chromosome; and (2) in the original su_{III}^+ strain, only *one* of them is altered (C for G) in one place (the anticodon).

The fact that both forms can exist for many generations means that *rectification does not take place* in *E. coli* at this locus.

The su₁₁₁⁺ strains are unstable and spontaneously revert

982 RECOGNITION AND CONTROL AT THE MOLECULAR LEVEL

at a high rate to the su_{III} condition, largely because of the deletion of one of the su_{III} genes, through an internal crossover event that deletes the su_{III} anticodon (Russell et al., 1970). A similar situation exists with *E. coli* strains capable of suppressing missense mutations in the A protein of tryptophan-synthetase (Hill et al., 1969, 1970; Brody and Yanofsky, 1963). Again, when one of a series of genes can be recognized by the existence of a mutational alteration, a high spontaneous reversion frequency is observed. Further examples of this can be found in the *E. coli* strains bearing multiple gal genes (Campbell, 1965).

Thus, in E. coli and phage, in which the chromosome (DNA) is not complexed with protective histone, the DNA is "freely recombining" (Thomas, 1966). There is some selective pressure (of significant but uncertain magnitude) to eliminate repetitive sequences by internal recombination. This idea is supported by the general finding that these strains are unstable, showing a high reversion rate. I formerly supposed that repetitions were prohibited for this reason (Thomas, 1966), but, as seen above, there is good evidence that some low level of tandem duplication is tolerated. Presumably, the strain balances the disadvantages of instability against the benefits of gene duplication, and the balance point is at one or a small number of duplications in bacteria and phage. A similar situation may occur at the ribosomal RNA locus; annealing experiments indicate several genes for rRNA (Yankofsky and Spiegelman, 1962). However, 100 or 1000 tandem repeats present a graver instability problem. Genomes of this type might have been impossible, had not histones developed to prevent internal recombination.

The protection of slaves from recombination may account for the observation that recombination between gene families is only 10 times more frequent than recombination within master genes. If both masters and slaves were equally sensitive to recombination, intergenic recombination should be 100 to 1000 times more frequent than intragenic recombination.

Summary In this section, the recombination rate between genes and within genes in Drosophila is shown to be in accord with The Theory. Chromosomal rearrangements are in general nondamaging in eukaryotes, but they are generally damaging in phage and *E. coli*. When the estimated number of genes is compared with the DNA content per genome, eukaryotes display an inordinately high amount of DNA per gene, whereas in phage one arrives at a reasonable value. Finally, a plausible role is suggested for histones—namely, to prevent recombination events among the slaves. Were they not so protected, they would suffer deletions by recombination, as is seen to be the case in prokaryotes. All these features of eukaryotes can be explained in terms of The Theory of the Master Gene. Unfortunately, none of these arguments is a strong reason for accepting The Theory, because each is weakened by counter arguments that I have largely ignored.

The chromomeric organization of chromosomes

CHROMOMERES AND MENDELIAN GENES Perhaps the most salient feature of the morphology of chromosomes is that they appear to be linear arrays of chromomeres. As the name implies, these are densely staining bodies, as seen in the light microscope. As mentioned above, the lampbrush chromosomes are organized into chromomeres. Belling (1931) observed a total of about 2500 pairs of chromomeres in the meiotic chromosomes of Lilium. He considered the chromomere as the structure in which individual genes were housed. The dipteran salivary chromosome is the classic exaggerated example of the chromomeric architecture of chromosomes (Figure 10). There can now be little doubt that these structures consist of 4000 to 8000 chromatids (DNA molecules) arranged in a parallel package, with all genetic regions in register. (This extreme example of polyteny is found in Chironomus and Rhynchosciara; in Drosophila there are probably 512 to 1024 chromatids per chromosome.) The banded pattern is thought to result from the fusion of the chromomeres of the individual chromatids. Bridges (1938) counted 1024 bands in the x chromosome from the salivary gland of D. melanogaster. Contemporary thinking held that each band represented a gene. Thus the x chromosome had about 1024 or more genes. There is now evidence that this may be a maximum estimation of the number of Mendelian genes, rather than a minimum (Beermann, 1967). Notice that this estimate of the number of genes agrees with the estimates based on uniform recombination (Table IV) and the other early estimates of gene number (Muller, 1929). An excellent account of this is to be found in Demerec's last article (1967). It is strange, indeed, as pointed out by Beermann (1967), that the chromomeric pattern of chromosomes has been ignored in speculations about their architecture.

The identification of chromomeres with Mendelian genes becomes more convincing in view of the fact that mutants can be correlated with the deletion of single chromomeres. Labeling with ²H-thymidine followed by autoradiography has revealed that the chromomeres themselves are units of replication (Plaut, 1969). Those chromomeres that contain more DNA seem to require a longer time to label, which suggests a limited number of growing points per chromomere. Finally, a study of the puffed regions shows that the chromomere seems to function in an all-or-nothing manner. Thus, as units of structure, mutation, replication, and expression, the identification of chromomeres with Mendelian genes would appear to be complete (Beermann, 1967).

So what's the problem? The chromomere contains too much DNA to be consistent with the 1000 nucleotide pairs

FIGURE 10 A comparison of the DNA contents in homologous bands of *Chironomus thummi thummi* and *C. thummi piger*. (Courtesy of H.-G. Keyl.)

required to specify an "average" protein. Rudkin (1961) estimated that there are 45,000 nucleotide pairs per chromatid in the smallest bands to 450,000 in the larger ones. This would correspond to 45 to 450 structural genes. From the presumed rate of movement of the giant-loop axis of chromosome XII in *T. cristatus*, Gall and Callan (1962) estimated that this chromomere contains a millimeter of DNA or more. This would correspond to 3000 genes; the number may be two or three times larger. The conclusion is clear: the observable chromomeres contain enough DNA to make hundreds and thousands of genes from the point of view of the molecular geneticist, yet they contain only *one* gene from the point of view of the Mendelian geneticist. The resolution of this dilemma is easy in terms of The Theory. The chromomeres contain gene families, each composed of hundreds or thousands of slaves. This resolution makes structural sense, as well. The tandemly-repeating sequences seen in Figure 1 would be expected to interact with the same kinds of histones to form a chromatin of regular repeating structure. Regular polymeric structures form helixes according to the general rules that govern the generation of such secondary structures as the α -helix, or double helix. Thus, chromomeres could be thought to be the natural structural consequence of a linear array of repeating units. Whether the unorganized interchromomeric regions represent "spacers" between gene families is not

known. It is significant that the interchromomeric space is rather uniform—0.1 to 0.2μ (see Beermann, 1967).

MUTATIONAL ALTERATIONS IN FAMILY SIZE Before leaving the subject of polytene chromosomes, I must mention the work of H. G. Keyl (1965a, 1965b). Chironomus thummi thummi and Chironomus thummi piger are so closely related that most of the bands in the salivary chromosomes can be correlated with one another. This identification is facilitated by the somatically paired salivary chromosomes in the F_1 hybrids.

Most homologous bands have the same DNA content, as measured by microspectrophotometry of Feulgen-stained preparations, but in 30 pairs of homologous bands there are striking differences. The C. thummi thummi bands sometimes contain 2, 4, 8, or 16 times more DNA than their homologous C. thummi piger bands. An example can be seen in Figure 10. Sometimes there is a variability within the "pure" C. thummi thummi population, in which certain homologous bands differ by 1:2 or 1:4. It appears that some relatively frequent event results in the doubling and redoubling of the DNA content of bands, yet no multiple other than 2^{N} is seen. Keyl interpreted this as the result of an error in replication-rejection of unequal recombination on the grounds that such a mechanism would lead to triplications or other nondoubling values. The results, however, are precisely what is expected from a recombination event if the chromomere contains a family of slave genes that form a single replicon (Figure 11). This model requires that the ends of the replicon be near each other, and that these most recently replicated ends be not yet fully protected from recombination by histone. As seen in Figure 11D, a single, nonreciprocal, recombination event leads to the (near) doubling of the family size. Notice that a nonreciprocal recombination of the opposite type leads to the deletion of all but a single gene (Figure 11E). Deletion of bands is, of course, a frequently recorded event-one that has played an important role in the correlation of the genetic map with the banded pattern of the salivary chromosome (see Swanson, 1957).

As can be seen in Figure 11E, nonreciprocal crossing over at the extremities of a gene family can either lead to a doubling of the family size, or to the deletion of all but one family member. Figure 11F-H shows how a crossover involving the alternate sister strands can account for the production of circular DNA molecules that contain almost a full gene family. Such a mechanism could account for the production of multiple copies of the nucleolar DNA, which is seen to be in the form of circular necklaces in *Triturus* oocytes (Miller, 1966). The amplification of special regions of the chromosome is seen in the "micronucleoli" of Hybosciara (Da Cunha et al., 1969). Thus, the chromomere doubling observed by Keyl, chromomere deletion, and the production of free circular DNA from certain regions of the chromosome may be alternative manifestations of a common mechanism—recombination between the terminal genes in a family.

There is another kind of increase in the DNA content of certain bands. Occasionally this is seen at the refusion point of certain inversions (see Keyl, 1965a). This observation is also in accord with The Theory. Consider that an aberrant breakage and rejoining event takes place between two different gene families. There is no assurance that this event will occur at a specific place, so subsequent rectification will lead to substantially *increased* or decreased family size, depending on the point of rejoining (see Figure 8). This process would not destroy any gene family that still retained its master. Thus, this interpretation is in accord with the finding mentioned above, that many (or most) chromosomal rearrangements are not damaging to genes situated near the refusion point.

The amount of nuclear DNA, evolution, and morphological complexity

According to current understanding, DNA is the sole carrier of hereditary information from one generation to the next. This being so, it would seem likely that there should be some simple relation between DNA content and information content. Although it is quite possible to measure the amount of DNA in cells, there is no known method of measuring the hereditary "information" in a biological object. As an only recourse, one turns to phylogenetic position or some qualitative feeling of "complexity." For example, the neural nets in a man are more complex than those in a fly and therefore must require more genetic information to specify them.

In Figure 12, the haploid DNA contents for a number of species are plotted against complexity (as I judge this mysterious quality). I suppose there would be no doubt that sponges are more complex than *E. coli*, that *Arbacia* and *Drosophila* are more complex than sponges. By the same token, a man is more complex than the lungfish. But birds and trigger fish are not obviously more complex than man! Nonetheless, Figure 12 is plotted this way. Even so, it makes no sense; it is a joke.

Such evidence has caused some persons to propose a nongenetic role for DNA. In an attempt to determine with what feature of the cell DNA was correlated, an interesting and obvious finding was made: DNA content is generally correlated with cell size and weight (for a recent contribution to this idea, which dates back to the last century, see Holm-Hansen, 1969), meaning that the amount of DNA is proportional to the amount of RNA and protein it specifies.

This finding does not support the notion that DNA is playing a nongenetic role: just the contrary.

Returning to DNA content and phylogeny, one can see certain trends if one stays within a single genus. Fishes provide an excellent example. There are more than 20,000 species of fish and room for more work; however, Hinegardner (1968) has reported assays performed on 200 species of teleost fish. DNA contents range from 4.4 to 0.4 picograms (pg) per 1C. Trusting that the lungfish has retained the DNA content (50 pg/1C) of its primitive ancestor, we can see that the DNA content of fish spans a 100-fold range. Hinegardner pointed out that the more ornamented and "specialized" the species is, the lower its DNA content. The same point, made by Mirsky and Ris (1951), is that advanced snakes contain less DNA per 1C than do more primitive snakes. On a larger scale, it is generally thought that reptiles have evolved from amphibians and birds from reptiles, yet as we pass from "primitive" amphibians to reptiles and then to birds, the DNA contents decrease by more than 60 times.

Barring the not unthinkable possibility that the present representatives do not resemble their archetypical forms in DNA content, we are led to the following generalization: as evolution proceeds and the forms become more specialized, DNA is discarded.

FIGURE 11 An interpretation of Keyl's results by recombination. A. A chromomere is shown schematically as a gene family, looped so that the termini are in apposition. B. Replication commences. C. Replication reaches the termini that are not yet fully protected by nucleoproteins. D. Recombination takes place, producing a doubling in gene-

DNA is discarded, but is information discarded as well? The loss of DNA could be attributed solely to a reduction in gene-family size, which would not lower the information content of the cell. Possibly, the amount of information could increase even with a decreasing DNA content. Finally, with our present level of understanding, there is no reason to deny the notion that, as specialization proceeds, genetic information is lost. Because of this latter possibility, it is not possible to build a strong case that the observed loss of DNA during evolution of species is due solely to discarding slaves.

On the other hand, some species, virtually identical in appearance and function, differ sharply in DNA content. For example, it is said that the spermatids of the amphipod crustacean *Gammarus pulex* contain three times as much DNA as those of *Gammarus chevreuxi*. The rhabdocoele

family size. E. A nonreciprocal recombination of opposite type deletes all but a single gene in the family. F. A recombination involving the alternate pair of sister-strands; compare with 11C. G. Produces a circular molecule containing nearly a full gene family. H. Products of such a crossover.

planarian Mesostoma ehrenbergi contains about 11 times as much DNA as does M. lingua, yet both species of planarian have the same number of chromosomes (Keyl, cited in Callan, 1967). The same kind of variation is observed among subspecies of Allium (Jones and Rees, 1968). In these cases, it seems very unlikely that the amount of genetic information varies substantially between the subspecies. This, again, is in accord with the idea that genes exist as gene families. The difference in DNA content can be attributed to a difference in the number of slaves per family, a proposal that is open to test.

A striking example that the differences in nuclear DNA content are due to differences in all the chromosomes is afforded by the work of Rees and Jones (1967). *Allium cepa* has 27 per cent more DNA per nucleus than does *Allium fistulosum*, yet they are so closely related that it is easy to

FIGURE 12 Haploid DNA contents per cell.

form fertile F_1 hybrids. In these hybrids, the meiotic chromosomes show aberrations in pairing at pachytene. Large, unpaired loops and overlaps are seen. At the first metaphase, all bivalents are asymmetrical, indicating that the chromosomes from one parent contain more DNA than those from the other parent (Figure 13), suggesting that rather insignificant mutational events can be responsible for large changes in DNA content. This observation resembles those of Keyl on polytene chromosomes (see above), and is susceptible to the same kind of interpretation.

Summary Variations in DNA content per nucleus appear to be unrelated to morphological or developmental complexity, possibly for three reasons: (1) it is not possible to relate the "complexity" of a biological object with genetic information; (2) specialization can be accompanied by a reduction in the number of different gene families; and (3) significant alterations in family size can occur without change in the number of families.

The evidence from annealing of polynucleotide chains

As is generally known, polynucleotide chains that are "complementary" in sequence will rejoin and reform a duplex molecule. Under favorable conditions, this process is extremely rapid (Studier, 1969a, 1969b), which is to be expected if "nucleation," the formation of the first few complementary base pairs, is the rate-limiting step (Thomas, 1966; Wetmur and Davidson, 1968). The "stability" of the reformed duplex depends on the length of the duplex, the type of base pairs, and the number and location of noncomplementary base pairs. There are only two ways known of testing the stability of a reformed duplex: (1) by measuring its thermal stability and (2) by testing its sensitivity to ribonuclease. The latter is useful only for DNA-RNA hybrid duplexes, and its specificity in this situation is not understood.

Even if the mechanism of the reaction is not understood,

FIGURE 13 Asymmetric meiotic bivalents of Allium cepa and A. fistulosum. Cepa has 27 per cent more DNA than fistulosum. A. Meiotic bivalents at first metaphase. Note that each is asymmetrical. B. An isolated pair of chromosomes. Note the loop (L) and the terminal overlap (O). (Courtesy of H. Rees; see Rees and Jones, 1967.) annealing experiments have been used widely for a variety of purposes, because there can be no doubt that the reaction depends primarily on complementary nucleotide sequences. Generally speaking, two different experimental situations have proved useful: (1) denatured DNA of high molecular weight is immobilized on nitrocellulose filters and labeled RNA or short, single-chain segments of DNA are annealed to the immobilized DNA; and (2) annealing of sheared, denatured DNA in bulk solution. The first type of experiment is generally concerned with the maximum amount of RNA that can be complexed with the fixed DNA in a state that survives ribonuclease treatment (Gillespie and Spiegelman, 1965). Presuming that the complexed RNA is united with the DNA chain to form a duplex hybrid, one calculates the fraction of the DNA that is complexed with RNA. Remembering the factor of two that enters because the known RNA species are complementary to only one of the two complementary DNA chains, the molecular weight of the RNA chains, and the molecular weight of the genome, one may calculate the maximum number of RNA molecules that can complex per genome. This is sometimes called "titrating the number of genes," which is permissible with a smile. Table V includes some representative findings doses of the NO region contain proportional increases in the observed number of RNA genes. In the case of *Xenopus*, the normal animal has 450 rRNA genes per 1C, but the anucleolar mutant has none.

Table V is in accord with The Theory. It predicts that, when purified messenger RNA molecules (such as those for hemoglobin or even synthetic RNAs) become available, they will complex with hundreds of genes per genome, just as is true for the other RNA species in Table V.

Visualizing Transcription The DNA-RNA hybridization experiments do not reveal the location or distribution of the genes in question. Nor do these experiments say anything about the arrangement of genes along the chromosome, although other lines of evidence indicate that they are arranged in tandem. The most unusual and compelling evidence is supplied by the recent electron micrographs of O. L. Miller, Jr., which show ribosomal precursor RNA in the act of being transcribed from nucleolar DNA (Figure 14). Here we see regular "plumes" of RNA, each pointing in the same direction and, with certain reservations, spaced at regular intervals along the DNA strand. Thus, it seems pretty clear that the rRNA genes are clustered and arranged in tandem. The current debate centers on the amount and

TABLE V
Number of Genes Per Genome for Known RNA Species As Measured
By Saturation-Hybridization Studies

	E. coli	Yeast	Drosophila	Xenopus	HeLa	Chicken

on ribosomal RNA, transfer RNAs, and the 5S RNA. As can be seen, in each case tested, there appear to be *hundreds* of genes for these RNA molecules in the higher organisms examined, yet only a few in *E. coli*. It might be thought that the large amount of rRNA that is complexed results from fortuitous complementary sequences at many places in the genome. Such is not the case, because mutants with specific deletions of the nucleolar organizer (NO) region have lost the ability to complex rRNA. Strains containing multiple function of the DNA intervening between the rRNA genes.

What can be said about the rest of the eukaryotic genome? Does it consist of repeated segments as well? When DNA from eukaryotes is highly fragmented, denatured, and annealed, it is now fairly clear that some kind of secondary structure is reformed. That structure has a lower absorbance at 260 m μ , and a thermal stability that is nearly (but not quite) as high as the undenatured DNA. This renatured material fractionates in a manner similar to that of

duplex DNA on hydroxyapatite, and a portion of it is resistant to nucleases that are specific for single chains.

Annealing experiments conducted in bulk solution are usually performed as follows: (1) the duplex DNA is sheared into segments containing several hundreds of nucleotide pairs (a rather substantial heterogeneity of size can be expected); (2) the segments are denatured by heat or alkali; (3) the solution is incubated at relatively high salt concentrations at a temperature 20° to 25° C below the melting temperature; and (4) the fraction of the DNA "renatured" is estimated by the absorbance (260 m μ) decrease or by altered chromatographic properties on hydroxyapatite. The fraction of material remaining in the denatured form (F) decreases as the incubation proceeds.

To interpret the rate of annealing, it is necessary to assume the following: (1) that the shear breakages occur at precisely identical points in all molecules, so that there are no singlechain overlaps on the reformed duplexes; and (2) that the length (L) of the single-chain segments is small in comparison with the length of the *nonrepeating* nucleotide sequence from which they are broken. With these assumptions, Wetmur and Davidson (1968) made the following formulation:

$$1/F = 1 + 1/2 k_2 P_0 t$$
,

in which P_0 is the initial concentration of nucleotide; k_2 the second order rate constant for the reaction, and t the time. A plot of 1/F against time generally gives a straight line for *E. coli* and phage DNAs, which are thought to be mostly nonrepeating. Assuming that each pair could be a potential nucleation point, they calculated

$$\mathbf{k}_2 = \mathbf{k}_{\mathrm{N}} \mathbf{L} / \mathrm{N}$$
 ,

in which k_N is the average rate constant for nucleation at each nucleation point. This equation means that the observed rate of annealing of chains of identical length cut from nonrepeating genomes should be inversely proportional to the number of nucleotide pairs in their genome. This expectation is generally confirmed with T7, T4, and *E. coli* DNA. With eukaryotic DNAs, the plots of 1/F against time are curved, indicating a heterogeneity in annealing rates. Part of the DNA appears to anneal very rapidly, another part more slowly, another part even more slowly. Components and rates must be estimated. In spite of the conceptual and experimental difficulties, certain qualitative conclusions emerge: a fraction of the singlechained fragments from many eukaryotic sources anneals at a rate that indicates a high and variable degree of repetition, unlike the nonrepetitive DNAs just mentioned (Britten and Kohne, 1968). In the case of mouse and hamster satellite DNA, the rate of annealing is very rapid indeed (Flamm et al., 1969a, 1969b).

A number of problems are presented in annealing-rate experiments. There are defects in the theory by which these experiments are interpreted. These come from the assumption that the re-formed duplex segments have no singlechain termini that can react further, whereas, in fact, reannealing short segments can produce structures of very high molecular weight. The experimental means of assessing the extent of renaturation are wanting: a lowered absorbance, or retention by hydroxyapatite, is not a faithful measure of the fraction of the nucleotides in duplex structure.

Finally, a conceptual problem, which applies equally to DNA-DNA and DNA-RNA annealing experiments, needs attention. It has been shown that ribonucleotide oligomers that are 12 or more units long will form a ribonucleaseresistant complex with homologous single-chained DNA (Niyogi and Thomas, 1967; Niyogi, 1969). It is likely that the same number applies for deoxyoligomers. There are only 8,388,608 different noncomplementary oligomers 12 units long. Yet mammals have at least 3,000,000,000 such oligomers (on one chain) per haploid nucleus, and amphibians have as many as 10 times more than do mammalian DNAs. Thus, each 12-unit oligomer must, on the average, be repeated 360 times. Will the presence of such oligomers, which are capable of forming stable duplexes, increase or decrease the rate of reformation of duplex segments? How do they affect the saturation levels in RNA-DNA annealing experiments? I don't think the answers are known.

A test for serial repetition of nucleotide sequences in duplex DNA

The experiments described above tell nothing about the arrangements of repeating sequences, because the fragments are smaller than the nonrepeating segment (L \ll N). In order to test the idea that sequences are tandemly-repetitious in eukaryotic DNAs, the length of the DNA fragments under study must be longer than the length of the repetitious unit $(L \gg N)$. This scheme is depicted in Figure 15. When segments of this type are denatured and annealed, circular DNA duplexes would be expected. Experiments of this kind have been performed to check this expectation (Thomas et al., 1970). Salmon and trout sperm DNA were sheared by being passed through a fine needle. Electron microscopy of the resulting preparation reveals linear molecules, 2 to 5µ long. Only rarely were circular structures seen with contour lengths in the 5- μ range. When this preparation is denatured, by either heat or alkali, and annealed, and then

FIGURE 14 Electron micrograph of ribosomal precursor RNA being transcribed from nucleolar DNA found in oocytes of *Triturus*. (Courtesy of O. L. Miller, Jr.)

FIGURE 15 Denaturation and annealing of tandemly-repeating DNA.

is examined by electron microscopy, many circular molecules are seen. Those from trout and salmon sperm DNA are shown in Figures 16 and 17. Their contour lengths ranged from 0.2 to 2 μ . To date we have photographed and measured about 200. If this experiment is repeated with prokaryotic DNAs, such as *E. coli* DNA or T7 DNA, essentially no circles are found. The few examples found have relatively long contour lengths (more than 2 μ) and are probably accidental arrangements.

We have attempted to measure the frequency and contour length of circles as a function of annealing time. Sheared trout sperm DNA was denatured and annealed for various periods of time, then passed through hydroxyapatite, and the second peak (containing partly-duplex DNA) was examined by electron microscopy. Circular molecules could be found after as little as 15 minutes of annealing. While the abundance of circular molecules increased with longer annealing, the distribution of contour lengths remained the same.

Some preliminary experiments indicate that segments of DNA of differing G+C composition will produce circles upon annealing. For this purpose, salmon sperm DNA was fractionated with respect to its melting temperature by "thermal chromatography" on hydroxyapatite (Miyazawa and Thomas, 1965). Each thermal fraction generated circular molecules, indicating that circle formation is a general property of all the chromosomal DNA, not just a certain compositional class of segments.

Special figures, more elaborate than circles, may be formed. What appears to be the next most complex structure is shown in Figure 18. Some of these, and their degraded derivatives, can be seen in Figures 16 and 17. These are the "mops" and tangled structures in annealed preparations of sperm DNA that are so hard to decipher. The prokaryotic DNA seems to produce cleaner linear structures.

FIGURE 16 Circular structures produced by denaturing and annealing trout sperm DNA.

992 RECOGNITION AND CONTROL AT THE MOLECULAR LEVEL

FIGURE 17 Circular structures produced by denaturing and annealing salmon sperm DNA.

FIGURE 18 More elaborate structures expected when tandemlyrepeating DNA is denatured and annealed.

The Analogy with Phage DNAs A phage DNA molecule is one that is cut to a length slightly longer than the nonrepeated segment. This is generally seen from the opposite point of view—that phage DNA molecules are terminally repetitious (see Thomas et al., 1968). When a nonpermuted collection of DNA molecules possessing a very long terminal repetition is denatured and annealed, many circles are found. An example of such a situation is afforded by phage T1 DNA (MacHattie et al., 1969). Indeed, phage DNA molecules that are permuted and repetitious provide a fragmentary analogy of the tandemly-repeating slave genes to be found in each gene family.

Summary In this section, some preliminary evidence is described that supports the notion that tandemly-repeating nucleotide sequences are a frequent occurrence in sperm DNA.

Rectification

Unless we can find some other logical alternative, the presence of tandemly-repeating genes means that some way must be found to account for the fact that recessive point mutants can be found in eukaryotes, and that alleles are inherited in an all-or-nothing manner as discrete Mendelian genes. To accomplish this, we hypothesize the existence of a master gene that *impresses* its nucleotide sequence on every slave in the family, about once every cell division. This process is called *rectification* in this paper. Rectification must take place in the germ line to account for Mendelian genetics. In view of the fact that crossing over can occur in somatic cells, and that the genes seem to be segregated as discrete units in this situation, as well (Stern, 1936, 1968; Pontecorvo, 1958), it is likely that rectification also must occur in somatic cells.

Such a concept is not pleasant—a master gene rectifying slaves. Some critics have suggested to me that there is no need for a master gene: it could all be done by democratic consensus! If so, it would be difficult to explain the appearance of recessive point mutants. For similar reasons, the idea of rectification seems to collide with preconceptions that are not completely scientific. Therefore, I wish to present a few possible models for this yet-to-be discovered process, and show that they are not at all unthinkable.

As a starting point, let us consider the "rolling circle" model for DNA replication that seems to account for some features of the replication of ϕx DNA (Gilbert and Dressler, 1968) (Figure 19A). It has been shown that one intermediate in the replication of mature T7 DNA molecules is a long, linear duplex up to four or more genomes in length. These molecules are almost surely concatenated genomes of T7 (Kelly and Thomas, 1969). One likely possibility is that they are produced by a "rolling circle" mechanism (Figure 19B). As can be seen from these diagrams, the nucleotide sequence in the tandemly-connected genomes is completely determined by the sequence in the closed "rolling circle." This closed polynucleotide loop is therefore the master gene that determines the sequence of the slave series. In the examples just given, the rolling circle contains an entire genome, but there is no mechanical reason why it could not contain only

FIGURE 19 Rolling circle models of DNA replication. A. To produce a repeating single chain as has been suggested for ϕx (Gilbert and Dressler, 1968). B. To produce a repeating duplex as has been suggested for T7 (Kelly and Thomas, 1969).

FIGURE 20 Models for rectification. A. Rectification by replication. B. Rectification by replacement and repair. C. Rectification by repair alone. The master gene is pic-

tured as a closed polynucleotide loop that rolls down the slave series, affecting replication or strand-selective repair.

a thousand or so nucleotides. This gives rise to the first model for Rectification by Replication (Figure 20A).

Rectification by Replication presents some difficulties, one of which is that there is no convenient way to tell it to stop! The gene family would be of uncertain size, and we know that total DNA contents (and the DNA content in the bands of the polytene chromosomes) is precisely specified. This scheme in unmodified form is a conservative mode of replication and does not fit with density-label shift experiments (Taylor, 1969).

To avoid these objections, we might suppose that Rectification by Replacement could take place (Figure 20B). In this model, a rolling circle (a master gene) rolls down a series of slaves, templating new DNA as it goes, and hydrolyzing nucleotides from the 5' end of the existing chain. In this model, one chain is specified by the master gene; the other is pre-existent. At this point, we must picture strandselective repairing to remove any existing nucleotide mismatches. This model would call for large amounts of DNA turnover, which does not appear to happen in somatic cells (Siminovitch and Graham, 1956; Healy et al., 1956) or during spermatogenesis (Lam et al., 1969).

To avoid this difficulty, we might suppose that Rectification by Repair occurred, which calls for a circular master chain to be looped into one of the two chains of the DNA duplex (Figure 20C). The circular master chain is pictured to roll down the slave family. When a base pair mismatch occurs, a strand-selective repairing system brings the sequence of the long chain into complementarity with the master chain. After the circular master chain is passed, a second step of strand-selective repair eliminates any mismatches with the first. Although strand-selective repair is not known at present, other strand-selective processes have been demonstrated, e.g., RNA transcription. Therefore, strand-selective repair is not outside the bounds of reasonable conjecture.

The purpose of these models is to show that it is possible to think of *rectification* in physical terms that are not unreasonable. I think that it will be possible to test some of these proposals. The most interesting prediction is that it should be possible to visualize the rectification apparatus in the electron microscope.

Evidence At present, there is no firm evidence for the existence of rectification. It is a logical requirement if we suppose that genes exist in multiple and functional form. There is, however, an observation made by Forget and Weissman (1969) who have sequenced the 5S RNA from a human epidermoid tumor, which would be expected to have multiple copies of the 5S RNA gene. They find *no* evidence for any heterogeneity in sequence; all the molecules appear to be identical. In sharp contrast, Brownlee et al. (1968) found that *E. coli* contains two forms of 5S RNA, and even further heterogeneity in sequence can be detected, as would be expected, if rectification were occurring in the human cells but not in *E. coli*.

Some implications of the theory

The implications of this theory are profound and touch almost every area of biology. The notion that there are about the same number of different genes in a fruit fly as there are in *E. coli* will not quickly be embraced by all biologists. The idea that a man has only about 10 times as many different genes as *E. coli* will receive an even less enthusiastic welcome. There are many reasons to be skeptical, because not a single argument that I have brought to support The Theory is completely convincing.

Immunoglobulins Clearly, The Theory impinges on our

current understanding of the specification of immunoglobulin sequences. In a sense, it inverts the question from What renders the variable portions of the light and heavy chains variable? to What causes the constant portions to remain constant? The Theory supplies the answer to the last question: rectification renders all genes in a family identical to the master gene. The origin of the variable gene, or genes, must result from a suspension aberration of the rectification process. In this way, mutational alterations could accumulate in this gene. Indeed, as was suggested to me by Edelman (see Edelman, this volume), if the rectification process could be held in abeyance for certain periods for special gene families, new opportunities for experimentation and subsequent selection would be made available at the subcellular level. Whether all this has anything to do with the specification of immunoglobulins is not clear. If anything, The Theory will supply new fuel for the model builders who are attempting to account for antibody specificity.

The Specificity of Self-assembling Neural Nets Those persons working on the organization of the nervous system are finding increasing evidence for the precise specification of very elaborate patterns of connectivity (Sperry and Hibbard, 1968; Jacobson, 1969, and this volume). If all these cellular connections were specified by different single genes, the number of genes required would be at least equal to the number of neurons (some 10¹¹ to 10¹² in man). On the basis of the DNA content of 3×10^9 nucleotide pairs, it might be imagined that there are 3×10^6 structural genes. Such a number is far too few, if each connection is to require a different gene product. According to The Theory, we must reduce this to perhaps 30,000 different gene families-or fewer! The problem is then rendered even more acute. A solution is obvious; nature must employ a code (see Griffith, 1967). Only 10 different gene products arranged in ordered sets of 12 will produce 1012 unique arrangements; or, 100 gene products arranged in ordered sets of six will give the same number. After all, thousands of different proteins are specified by only four nucleotides. Therefore, there is no reason to reject the notion that a man has only 30,000 different genes simply because his neural net is highly specified.

Prospect If it be presumed that The Theory is generally correct, the most significant implication is excitement. If the genetic complexity of man is only 10 times greater than $E. \ coli$, there is a real chance that we shall soon understand as much about his biochemistry as we now do of $E. \ coli$. The task before us may be 1000 times easier than we feared.

Acknowledgments

Writing this paper has been an exercise in learning. Many people have given me assistance and sometimes encouragement. Oscar Miller, Jr., and through him J. G. Gall, have been most helpful. Ed Lewis and Sol Spiegelman have brought many items to my attention. I thank Professors H. Rees, H. G. Keyl, J. G. Gall, and O. L. Miller, Jr., for their photographs. This work was supported by the National Science Foundation (GB-8611) and the National Institutes of Health (GM-08186). I am also indebted to my colleagues who debated these issues with me over many months: Garret Ihler, Barbara Hamkalo, Barbara Otto, Roy Barzilai, Lorne MacHattie, Larry Okun, and Gene Kennedy. A former laboratory technician, Mrs. Cindy Kelly, took some of the electron micrographs included here: Dr. Hamkalo, the others. Jackie Vaughan deserved a medal for seeing the various drafts through to this stage. Finally, I express my appreciation to Professor H. G. Callan, whose papers stimulated my interest in this subject.

87 Structure and Replication of Eukaryotic Chromosomes

I. HERBERT TAYLOR, WILLIAM A. MEGO, and DONALD P. EVENSON

DURING THE LAST 15 years, enough new information has been obtained to allow reasonable predictions concerning the organizational and regulatory features of chromosomes. Although much of our understanding of the properties of DNA and genetic regulation has come about through the analyses of viruses and bacteria, attention in this presentation is given to higher cells, i.e., the cells of eukaryotes. The principal evidence is drawn from mammalian cells, with background information from prokaryotes in mind, but seldom referred to directly. Perhaps the most important generalization about these two cell types is that prokaryotes, which lack true nuclei and are represented by a number of viruses and a few bacterial species that have been studied extensively, maintain a single copy of most genes; in eukaryotes, which have true nuclei, mechanisms have evolved for handling multiple copies. In addition, eukaryotes possess nuclear membranes, nucleoli, histones associated with their DNA, and chromosomes that condense into rod-shaped bodies during mitosis.

Britten and Kohne (1968) have reported that 10 per cent or more of the DNA of mammalian cells reanneals after

J. HERBERT TAYLOR, WILLIAM A. MEGO, and DONALD P. EVENSON Institute of Molecular Biophysics, Florida State University, Tallahassee, Florida

shearing and denaturing at a rate which indicates that each genome contains about a million copies of very similar sequences. No such repeating sequences are found in viruses, bacteria, blue-green algae, or other prokaryotes. However, an examination of more than 50 species of eukaryotes distributed among many classes of both the plant and animal kingdoms revealed fast reannealing fractions of DNA. This observation indicates a striking difference between the prokaryotes and the eukaryotes. According to these authors, most other base sequences in the DNA of eukaryotes are represented by no more than 10 copies. Although these data give us only an order of magnitude for redundancy in the genetic apparatus, they lend a rather convincing argument to other circumstantial evidence, cited by Thomas in this volume, that higher cells contain numerous copies of each genetic locus. The number of copies is assumed to be relatively small in an organism such as Neurospora, which has only 10 times as much DNA per genome as does the prokaryote Escherichia coli. Mammalian cells have nearly 1000 times the amount of DNA that is in a cell of E. coli, but the record is held by the lungfishes and certain amphibians, which have 30 to 40 times as much DNA as does the mammalian cell (Taylor, 1969a).

The problem posed in the maintenance of multiple copies has been considered by Thomas. He has elaborated and modified the concept of the master gene, a hypothesis originally suggested by Callan and Lloyd (1960) and treated in detail by Callan in 1967. This proposal is that multiple identical copies of genes can exist in spite of independent mutation, because the master gene periodically corrects to its base sequence the whole cluster of genes associated with it. This is done by some repair or base substitution process to make the slaves (multiple working copies) match the master copy.

It is still difficult to explain the fast reannealing fraction by this concept of multiple copies, for there are too many similar or identical copies of one type-about one million per genome for the mammalian cell. Some animals have a satellite band of DNA, i.e., a density species that bands in CsCl or other cesium salts at a different position from the main band of DNA. A light satellite in the mouse has been studied extensively by Flamm et al. (1969). It reanneals more rapidly than does the main-band DNA, and may provide a clue to the fast reannealing fraction. Maio and Schildkraut (1969) have found that the satellite DNA is distributed about equally among the various chromosomes of the mouse. Flamm et al. (1969) also found that satellite DNA hybridizes to some extent with main-band DNA. However, one of the most revealing features may be their finding that cytoplasmic messenger RNA does not hybridize with the satellite DNA. In addition, they found some indication that the fast reannealing fraction in rodents drifts faster in evolution than do the less numerous sites. For example, satellite DNAs

in mice and guinea pigs hybridize proportionately less well than do their main-band DNAs.

We have examined the subunits of DNA released from chromosomes by various treatments and manipulations. We believe we have found the basic repeating unit, which is about 2 microns long. Circumstantial evidence indicates that it contains five segments united by more flexible regions of the DNA. We propose that the fast reannealing fraction of DNA is produced by one of the five segments that consists primarily of adenine- and thymine-containing nucleotides, which we refer to as the A-T segment. Some additional assumptions are necessary to explain the satellite DNAs, but we shall come back to this problem after presenting some new information on the size and characteristics of DNA subunits in chromosomes. Because of space limitation, the material must be presented with a minimum of documentation. After presenting the concepts on the organization of chromosomes, we shall make some preliminary suggestions concerning possible functions of the genetic apparatus peculiar to neurons.

Subunits of DNA from chromosomes

80S SUBUNITS The chromosomal DNA in Chinese hamster cells can be dissociated into large subunits, which sediment as a single, rather narrow band in a sucrose gradient (Figure 1). For example, nearly all the DNA from rapidly

FIGURE 1 Profile of DNA in an isokinetic sucrose gradient, i.e., one designed so that the change in density and viscosity of the solution compensates for the increase in centrifugal force along the length of the tube. The distance of a sedimenting band from the center of rotation is linearly related to the sedimentation coefficient (S). All subsequent sucrose gradients are of this type. This particular gradient shows the sedimentation of dissociated hamster DNA (open circles) and a marker, phage T-4 DNA (closed triangles). The DNA was spun in the Spinco SW 27 rotor at 21,960 rpm for 10 hours at 20° C in 1 M NaCl buffered at pH 9.5 with tris-EDTA and sucrose.

growing, log-phase cells or from metaphase chromosomes and G1-phase cells can be dissociated into these subunits at pH 9.0 to 10.0 in 0.15 м NaCl after deproteinization by exhaustive pronase digestion. The band of hamster DNA is not appreciably wider than that formed by the marker T-4 DNA used in the gradients when care has been taken to avoid mechanical shear in the lysis and subsequent handling. These results have been obtained many times after a variety of treatments to bring the DNA into solution, including lysis at 0° C with sodium dodecyl sarcosinate in viscous sucrose solutions. However, lysis at 37° C without sucrose or other viscous materials gives similar results, if the DNA is handled carefully and pipetted very slowly through a widemouth pipette. Preparations have also been made by lysing the cells in a centrifuge tube and floating the lysate on a sucrose solution delivered into the bottom of the tube to avoid pipetting the DNA. All methods give similar results, except that aggregation of the DNA often leads to the loss of much of the material by rapid sedimentation to the bottom of the tube. The pronase digestion is not necessary to obtain dissociation if the pH is raised to between 10 and 10.5. Without deproteinization, however, the yield of material that remains in the gradient is usually poor. One of the most important considerations is the lysis of cells at a dilution of not more than about 106 cells per 10 milliliters, i.e., at about 1 microgram of DNA per milliliter. More concentrated lysates can be diluted, but the sedimentation properties are often variable. DNA should not be stored in the cold in the presence of a detergent that will precipitate, because the DNA also comes out of solution. Once out of solution, the DNA is very difficult, if not impossible, to dissolve without shear and consequent breakage. Entanglement of the long strands must be avoided. Even very slow rolling of the tube usually leads to entanglement and aggregation.

These large subunits of DNA sediment with a peak at 80S, which indicates that they are about 100 to 110 microns in length, i.e., nearly twice the length and molecular weight of intact molecules of T-4 DNA. Although the exact molecular weight and uniformity of these subunits cannot yet be proved, we refer to them for convenience as the 80S, or 110-micron, subunits. The mechanism by which they are dissociated cannot be stated with any assurance, but to us it appears unlikely that they are linked by protein. Perhaps a double-stranded DNA in a region with single-stranded interruptions on either side melts, or a region that is extremely fragile to shear exists at the sites of dissociation. Longer pieces of DNA have been indicated by autoradiography (Cairns, 1966; Huberman and Riggs, 1968), but the relation of these pieces (1 to 3 mm long) to the subunits obtained by dissociation is not evident. Larger aggregates probably occur in our lysates, but no quantitative information can be obtained until these dissociate as described. It is possible that 80S subunits represent structural units of the chromosome,

for they contain the amount of DNA that might be in a loop formed by the nucleoprotein fibrils (230 Å in diameter) that have been identified in chromosomes and interphase nuclei by DuPraw (1968). On the basis of mass per unit length and the estimated composition of nucleoprotein in the fibrils, he has estimated that the packing ratio is 56:1 for DNA. Because the nucleoprotein loops are about 2 microns long in metaphase chromosomes of mammalian cells, they contain perhaps one of the 110-micron subunits of DNA.

We have spent considerable time trying to separate the strands of these 80S subunits of double-stranded DNA, but the results so far have been confusing. If they are banded in an alkaline sucrose gradient (pH 11.6 to 12.0) without digestion of the lysate with pronase, they have nearly the same sedimentation rate as have the native particles (Taylor, 1969b). Under similar conditions, the chains of the marker T-4 DNA will separate and produce a band with a peak at about 45S to 46S. We conclude that strand separation does not take place, although the hypochromic shift, which indicates denaturation, occurs between pH 10.5 and 11.5 in these sucrose solutions. When lysates are digested exhaustively in pronase (1 milligram per milliliter) at 37° C at pH 9.0 for from six to 12 hours, the strands apparently separate and produce a rather wide band, with a peak at about 30S (Figure 2). These pieces have an average length of about 20 to 22 microns, and their lengths indicate that each chain of the 80S subunit can be dissociated into five subunits in alkaline gradients. However, care must be taken to obtain this separation. The pH must be above 11.6, and the best results are obtained by raising the pH before layering lysates on gradients, preferably by dialysis. Our results also indicate

FIGURE 2 Profile of DNA in a sucrose gradient at pH 11.8. The hamster DNA (broken line) was from a stationary phase cell culture, and the marker (solid line) is DNA from phage T-4.

that the DNA of higher cells is broken by alkaline solution, in contrast to the marker T-4 DNA, which appears stable at pH 11.5 to 12.0 for many hours at 10° to 20°C. The hamster DNA is broken very slowly at 10°C and rather extensively at 37°C.

Attempts to separate the chains by nonalkaline solutions have so far met with only limited success. A gradient of sodium trichloracetate (TCAate) was prepared that was nearly isokinetic, 2.1 M to 3.18 M. Cells were lysed in a solution of 1.5 M TCAate, with EDTA (ethylene-diaminotetracetic acid) and SDS (sodium dodecyl sulfate). The DNA was exposed briefly to 3 M TCAate at 37° C and then centrifuged through the gradient at pH 9.5 at 20° C. The sedimentation coefficient of the marker T-4 DNA was calculated to be 43S and that of the hamster DNA to be 57S (Figure 3). However, the sedimentation coefficient of the hamster DNA is actually 58S to 59S (if one assumes that the T-4 strands separated and had the expected S value of 45 to 46); this value of 58 to 59S indicates a particle about one-half of the size of the 80S double-stranded unit. Therefore, our tentative conclusion is that most strands in the 110-micron (80S) subunit are uninterrupted. An attempt to sediment DNA from G₁ cells through a DMSO (dimethyl sulfoxide) sucrose gradient gave a rather broad distribution, with a peak about 62S to 63S. This should be the denaturing solvent of choice for deciding the question of the size of the single-stranded units. The large polymer is difficult, however, to keep in solution during transfer to these nonaqueous solvents, and more work is necessary to get reliable evidence.

FIGURE 3 Profile of DNA in a TCAate gradient at pH 9.5. The hamster DNA (closed triangles) was isolated from cells at the G_1 phase, and the marker (open circles) is DNA from phage T-4.

TWO-MICRON SUBUNITS We have usually used synchronized cells for our studies so that we could characterize the DNA in relation to the stages of the cell cycle. In Chinese hamster cells, these stages are as follows: division stages (30 to 45 minutes), G1 (the gap between division and the beginning of DNA replication, five to seven hours), S phase (the period of DNA replication, six hours), and G2 (the gap between the end of DNA replication and the next division stages, two to three hours). We noted rather early in our studies that DNA in alkaline gradients frequently showed a small band of particles with a peak at 10S to 12S (Figure 2). These were seen in DNAs from interphase stages and telophase, but not in DNA from metaphase chromosomes. The small segments were also seen in cells synchronized in S phase, but the short chains were composed primarily of template DNA (labeled the previous cell cycle) rather than newly formed strands. Therefore, it was not originally considered a functional unit in replication, but was thought to be a unit of transcription. Later, one of us (Mego) found that the short pieces were much more abundant in static cultures, i.e., cells inhibited by crowding and perhaps by a deficiency of essential nutrients. The cells could recover when transferred to new medium, and the small pieces would decrease in frequency before the cells entered the S phase. Even more revealing was his discovery that double-stranded pieces about 2 microns long, sedimenting with a peak at 15S, could be dissociated from the DNA of these static cells by being heated to about 65° C in 0.1 to 0.15 M NaCl and cooled before centrifugation through a sucrose gradient (Figure 4). In most instances, formaldehyde was added dur-

FIGURE 4 Sedimentation profile of hamster DNA in a gradient at pH 9.5. The DNA was isolated from Chinese hamster cells (strain B14FAF 28-G3) in a culture that had reached a static condition or nearly stationary growth phase because of crowding and partial depletion of nutrients in the medium. The DNA was heated to 65° C with 1 per cent formaldehyde before being cooled for centrifugation.

EUKARYOTIC CHROMOSOMES 1001

ing or after heating to increase the yield. This indicated to us that single-stranded nicks occurred at regular intervals in each strand, but alternated in position so that two breaks were not opposite each other (Mego and Taylor, 1969). The overlap regions melted out at a low temperature, which suggested that they contained a high proportion of adeninethymine (A-T) base pairs. The rather uniform size of the subunits suggested that these high A-T regions occurred at regular intervals along the DNA strands.

More recent results (see section on replication below) have revealed small amounts of a 15S to 18S fraction, which contains newly replicated DNA after a pulse label of cells synchronized in the S phase. This leads to the concept that the 2-micron subunit is the basic unit in replication. There would be about 55 of these units (2 microns in length) per large 110-micron segment of DNA; these are probably organized into subgroups of 10 to 11 units each, which have a tendency to separate under alkaline conditions to give singlestranded fragments about 20 to 22 microns long (30S). There would be five of these subgroups of 11 per 110micron subunit. As mentioned below, this unit of 11 2micron subunits is thought to be a structural and functional grouping of some significance in regulation of replication, but, as stated above, the 2-micron segments are probably the basic replicating unit. Each is believed to be composed of a high A-T region and four other regions about 0.4 micron long, with a flexible joint between. We have seen these joints occasionally in our electron micrographs, and they were predicted on the basis of hydrodynamic evidence (Gray and Hearst, 1968). If one assumes that the region of high A-T content is the same size as the other four units, which are assumed to have the four bases in nearly equimolar ratios, the peculiar base composition of eukaryotic chromosomal DNA is predicted. One-third of the thymine is in the A-T segment, and about one-sixth is in each of the other four segments. The A-T segment almost certainly has a small number of G-C base pairs, because a few G-C base pairs have been found even in the A-T satellite obtained from the crab (Davidson et al., 1965). This distribution of segments predicts an average base composition of about 40 per cent G-C, which, with few exceptions, is typical of eukaryotes.

SMALLER SUBUNITS OF REPLICATION When Chinese hamster cells are given a two-minute pulse of ³H-thymidine, a large part of the label is incorporated into a fraction that is detached from the high molecular weight DNA in lysates. The small pieces of DNA can be isolated in sucrose gradients of lysates, but a better preparation is obtained by removing the high molecular weight DNA with hydroxyapatite. One fraction (I) does not attach to the hydroxyapatite in 0.05 M phosphate buffer at pH 7.0 (Figure 5). This fraction sediments with a peak near the top of the gradient

(about 2S), as shown in Figure 6. Another fraction elutes off the hydroxyapatite in phosphate buffer, pH 7.0, at concentrations between 0.10 and 0.16 м (Figure 5). This is the region over which single-stranded DNA is eluted. These pieces sediment with a peak at about 7S (Figure 6). The small pieces of DNA that are precipitated in 5 to 10 per cent cold trichloracetic acid (TCA) are held up in BioGel P-30 and P-10 when raised to pH 12.0 to denature before being filtered through the column. They are excluded from Bio-Gel P-2. On this basis, a size of about 10 nucleotides in length is suggested (Hohn and Schaller, 1967). The 7S material is excluded from BioGel P-60 and appears in the fraction equivalent to the void volume of the gel. It is retarded by an agarose gel designed to retard globular molecules with molecular weights between 10^4 and 5×10^6 daltons. No conclusions concerning its maximum size can yet be drawn from the gel filtration. From its sedimentation, one can estimate the length of the 7S material as equivalent to a polynucleotide of 1000 or more nucleotides.

To summarize, then, we think there is a hierarchy of significant subunits. To begin with the two smallest, which have been detected only during replication, there is a presumptive initiator-primer unit of perhaps 20 to 30 nucleotides, in addition to the much larger 7S unit, which is released as a single strand in lysates. Probably the initiators consist of at least two partially complementary polynucleo-

FIGURE 5 Elution of pulse-labeled DNA from a hydroxyapatite column. Fraction I did not adhere to the hydroxyapatite in 0.05 M phosphate. Fraction II is single-stranded DNA, and fraction III is double-stranded. (From Schandl and Taylor, 1969.)

FIGURE 6 Sedimentation profiles of fractions I and II (similar to those shown in Figure 5) run separately in two sucrose gradients, pH 11.8. Only fractions from the top of the tube are shown, as most of the labeled DNA consisted of these rather small pieces. The material that failed to adsorb on hydroxyapatite was rather heterogeneous with respect to sedimentation properties, but a striking peak produced by small polynucleotides is evident near the top of the gradient, fraction I. The single-stranded DNA (fraction II) is more uniform in size (from Schandl and Taylor, 1970).

tides, as shown in Figure 7. We have assumed that a group of nonmatching base pairs is maintained to produce the flexible joints. The mechanism proposed to maintain this irregularity is the insertion of a primer-initiator subunit at the junctions between each 7S subunit.

A group of five 7S subunits (9S, if double stranded) is assumed to make up one 2-micron (15S) subunit (Figure 7). An electron micrograph of a 2-micron subunit is shown in Figure 7A. Many short segments of DNA were observed in a protein film (cytochrome-C spread on a water-air interface) prepared from a sucrose gradient similar to that shown in Figure 4. Other stiff, double-stranded DNA segments shorter and longer than this one were observed, but most of the particles were 1.6 to 2.4 microns in length. A spacing of readily denaturable regions 0.3 to 0.5 micron apart was observed in the DNA, which was heated to 55° C in 11 per cent formaldehyde dissolved in 0.01 M phosphate buffer at pH 7.0. The DNA was cooled quickly, spread on a waterair interface in a film of cytochrome-C for two minutes, picked up on a carbon-coated grid, and stained with uranyl acetate. The most frequent center-to-center distance between melted regions was about 0.5 micron, but another modal frequency occurred at 0.9 to 1.0 micron. However, long segments of the DNA failed to open in this fashion. Only additional studies can indicate whether the failure was the result of fluctuations produced by the manipulations or actual variations in structural features.

In some cases a large denatured segment, 0.3 to 0.5 micron, was found adjacent to three or four smaller openings (Figure 7B). We have assumed that the structural features may have a regularity, and have designated the five segments assumed to compose a 2-micron subunit as 1, 2, 3, 4, and 0 (Figure 8). One, 2, 3, and 4 are assumed to be coding sequences, and the presumed high A-T regulatory subunit is designated 0. A cluster of 10 or 11 2-micron subunits forms a group that can be dissociated and is seen as single strands in alkaline gradients (30S). When double-stranded, the pieces sediment with a peak at 40S to 41S. The largest dissociated subunit is the 80S (110-micron) subunit, which consists of about 55 of the 2-micron units in five clusters. These 2-micron subunits would be our choice for the repeating unit in the chromosome, but the larger clusters may have some regulatory features in common, probably in both replication and transcription.

The compact folding of the 2-micron DNA subunits is visualized as consisting of a stack of five flat platelets with a considerable portion of the protein between them. Each platelet is formed from one of the 0.4-micron regions between the flexible joints. The DNA is assumed to be folded eight or 10 times in each platelet to form nine or 11 parallel cylindrical rods, a type of packing indicated for crystals that have been prepared from a solution of DNA (Giannoni et al., 1969). The high A-T segment forms the first layer, and a flexible joint allows transition to the next layer of identical size. Five layers finish the nucleoprotein segment, and the attachment of a replication guide (probably a nonhistone protein) marks the transition to the next 2-micron subunit. The platelets formed of the high A-T DNA would alternate along the nucleoprotein fibrils so that, in each stack of five, the A-T platelet is on the opposite side of the fibril from the platelets in its two neighboring 2-micron subunits. Although one must concede that the picture drawn is a bit fanciful and idealized, it fits the available evidence and gives us a pleasing model to test.

Replication of chromosomal DNA

Replication takes place over an interval of the cell cycle that is remarkably uniform in many kinds of mammalian cells, both in vivo and in vitro. The interval is about six hours in cell cycles, which may vary from 12 hours to many days. Both the S phase and the length of the G_2 and mitotic stages are rather uniform. The variable stage is the G_1 phase, i.e.,

FIGURE 7 Top. Electron micrograph of a segment of native DNA from the 15S peak of a sucrose gradient similar to that shown in Figure 4. The DNA was prepared for microscopy by spreading in a film of cytochrome C on 0.15 M ammonium acetate by the method of Kleinschmidt

(1968). Bottom. Electron micrograph of a segment of DNA which was heated at 55° C in 0.01 M phosphate buffer, containing 11 per cent formaldehyde pH 7.0, for 10 minutes, quickly cooled and spread in a film of cytochrome C on 0.15 M ammonium acetate.

FIGURE 8 Diagram of the proposed structural arrangement in the 2-micron subunits of DNA. Each subunit is shown to be composed of five 7S segments, which are shown in greater detail in the second figure. These segments are coupled by the initiator segments shown in detail in the lower figure. The squares show the position of the hypothetical replication guides, presumably protein with a high affinity for the DNA, at the opposite ends of each 0 segment.

1004 RECOGNITION AND CONTROL AT THE MOLECULAR LEVEL

the interval between the shift from telophase to interphase and the beginning of DNA synthesis. Once synthesis is initiated, most cells appear to be committed to a programed sequence of events that leads to another mitosis, unless some unusual intervention takes place. Few, if any, measurable parameters reveal a sequence of events in the G1 phase, even though a number of steps appear to be necessary before the cell is committed to a new cycle of division. Perhaps the cell remains in an uncommitted stage-which Lajtha (1963) would call the G₀ phase-until a stimulus initiates events leading to DNA replication and division. As a result of autoradiographic studies of chromosome reproduction, it became clear a number of years ago that not all chromosomes or sectors of the same chromosome have their DNA replicated over the relatively long time interval of six hours (see a review by Taylor, 1969). The long arm of the X-chromosome of the Chinese hamster, for example, completes replication in the last three hours of the S phase. Within this and other chromosomal segments are many units that replicate independently, some simultaneously and others out of phase. Precise programing of the various units may occur during the regular replication cycle, and a few sectors have been demonstrated to replicate repeatedly at a precise stage related to development in specialized cells. Examples are the ribosomal-RNA coding portions of the DNA in oocytes and a few regions of salivary-gland chromosomes of Sciara, Rhynchosciara, and perhaps other dipteran genera. In any case, there is enough information to indicate a highly evolved regulatory system for replication that is intimately involved in differentiation and various functional aspects of transcription.

Several studies have indicated that, during replication, new DNA chains in mammalian cells increase in length at the rate of 1 micron to 2 microns per minute. One of the most direct methods is the measurement of the increase in length of new polynucleotide chains in cells synchronized at the beginning of the S phase. The new chains can be detached from the template in alkaline sucrose gradients (Taylor, 1969b), and the lengths estimated from sedimentation rates. Elongation is more-or-less linear with time up to about 20 or 30 minutes. However, when cells are synchronized by blocking, for a few hours at the beginning of the S phase, with fluorodeoxyuridine (FUdR) and then released with thymidine, the initial rate of chain growth may be faster than usual. Our recent data indicate that rates can vary from 1 micron to 2 microns per minute. The faster rates may result from the simultaneous replication of several small subunits, which are later joined enzymatically. Huberman and Riggs (1968) reported autoradiographic studies on patterns of labeling which indicated that chain growth may proceed from a point and move in both directions. They exposed cells, partially synchronized by blocking with FUdR for 12 hours, to 3H-thymidine of very high

specific activity for 30 minutes. When cells were lysed and the DNA was extended on a membrane filter, an autoradiograph showed streaks of grains in tandem. Each group of grains presumably represented segments of DNA, which grew in the 30-minute interval. The lengths were consistent with growth rates of 0.5 micron to 2 microns per minute, but a more interesting observation was the labeling patterns of DNA from cells removed from the ³H-thymidine so that the specific activity of the DNA precursor dropped while the DNA chains continued to grow. The relatively dense rows of grains then showed a decreasing number of grains per unit length at both ends of many segments. From this observation they proposed that growth was taking place from both ends of the new chains. If they are correct, a measure of the rate of increase in length of new chains by sedimentation in a sucrose gradient would give a rate twice the true rate of chain growth.

The discovery that replication proceeds by the production of many short segments, the 7S subunits, could make our concepts of chain growth obsolete. A variety of evidence in both prokaryotes and eukaryotes, however, indicates sequential linear growth over many microns of DNA. These observations, in addition to our recent evidence that the 2-micron subunit may be a unit of replication, leads to the following proposed scheme of replication. Other circumstantial evidence, cited below, also fits into the proposed scheme.

Our present picture of replication is that initiation occurs by opening one strand of the template at the right or left terminus of an A-T segment. These regions are assumed to be self-priming, as shown in Figure 9, i.e., initiation does not require a small polynucleotide to fit on the template to initiate chain growth. Yet, we find small polynucleotides in pulse-labeled cells, as pointed out in the previous section. The evidence for this assumption of self-priming segments is not strong, but it allows us to explain partial replicas,

FIGURE 9 Diagram of a segment of DNA containing one 2micron subunit and its two adjoining subunits. Replication has been initiated and is proceeding from left to right. Note that strand growth is always produced by addition of nucleotides at the 3' OH end of chains as described in the text.

which are stable for hours in cells with perturbations in replication (see evidence presented in the next section). Furthermore, Bollum's studies (1967) of in vitro DNA replication indicate that denatured DNA is self-priming and forms new chains covalently linked to the template.

One plausible model is shown in Figures 8 and 9. A sequence of adenine-containing nucleotides to the right of an initiator segment could provide a region complementary to the terminal nucleotides at the end of each 2-micron subunit. A replication guide, pictured as a protein coupled to specific nucleotides beyond the terminus of the 2-micron subunit, might specify the locus at which a nuclease opens the chain and, at the same time, permanently blocks the movement of a growing point past its locus. The only alternative would be for the initiator end to bend back and allow its five terminal thymines and one cytosine to pair with the guanine and five adenines just to the right. This self-priming feature is assumed to be unique for the A-T segment. At the opposite end of each A-T segment is another initiator segment assumed to be capable of selfpriming in a similar way. Operation of both sites simultaneously, however, would probably be excluded, because that would probably lead to the fragmentation of the DNA and chromosome breakage. Simultaneous attachment of a replicase and pairing as indicated above would initiate replication that would proceed to the end of the A-T segment. At that point, growth would stop unless an initiator-primer segment were available. In other words, segments 1, 2, 3, and 4 are not assumed to be self-primed. Presumably they are initiated in sequence, although such a requirement is perhaps not necessary. It is presumably these segments (7S subunits) that are displaced when pulse-labeled cells are lysed and yield the 5S to 7S single-stranded segments (Schandl and Taylor, 1969, 1970). The labeled initiatorprimer segments are also detected in pulse-labeled cells, and separate as a distinct band near the top of sucrose gradients (\sim 2S). The 2-micron subunits are assumed to be initiated in sequence, and growth probably takes place in both directions from a single 2-micron subunit.

Data, which support this model and indicate the importance of the 2-micron subunits in replication, are presented in Figure 10. It shows the profile in a preformed sucrose gradient at pH 9.5 of the particles of DNA labeled in a two-minute pulse with ³H-thymidine in Chinese hamster cells synchronized at the beginning of the S phase. The DNA was heated to 65° C in the presence of 11 per cent formaldehyde at pH 9.0 to dissociate subunits held together by pairing of base sequences, which melted well below the average melting temperature of the chromosomal DNA. Near the top of the gradient are the small subunits typically found after a short pulse of ³H-thymidine. The region of the gradient of interest here, however, is that with particles 18S to 20S, i.e., to the right of this band of smaller particles,

FIGURE 10 A sedimentation profile in a preformed sucrose gradient of ³H-thymidine-labeled DNA isolated after a twominute pulse of Chinese hamster cells in culture. The cells were lysed and the proteins digested as completely as possible with pronase. A dilute solution of DNA (1 μ g/ml) was heated for 15 minutes to 65° C in 11 per cent formaldehyde dissolved in 0.10 M NaCl buffered at pH 9.0. The solution was rapidly cooled before layering on a preformed sucrose gradient.

7S to 9S. Examination of DNA from this region by means of electron microscopy reveals segments about 2 microns long with single strands attached at the ends of the doublestranded positions. We believe these are the subunits caught in the process of replication, but far enough advanced to have part of the new, growing chains attached to the template, as shown in the diagram in Figure 9.

Partial replicas of the 2-micron subunits

Although the 2-micron subunits are assumed to be initiated in sequence to produce the long chains of DNA detected in alkaline gradients, the evidence from incorporation of a density label into DNA indicates that interruptions in such sequential growth can occur. When cells are forced to substitute bromouracil for thymine during an interval by blocking the synthesis of thymidylate with FUdR and supplying bromodeoxyuridine, a density hybrid DNA appears, but various partially substituted satellite bands also can be demonstrated (Haut and Taylor, 1967; Taylor and Miner, 1968). Even when the lighter or heavier bands do not separate clearly from the main band of DNA in a CsCl gradient, their presence can be detected as a shoulder on the light or heavy side of the main band. In a typical experiment, a density hybrid DNA labeled with ¹⁴C is produced by forcing the complete substitution of bromouracil for thymine. Figure 11 shows such a distribution of Chinese

hamster DNA in a CsCl gradient produced by spinning a solution of DNA in the appropriate concentration of CsCl for 48 hours. Hybrid DNA and any other partially substituted DNA is labeled with ¹⁴C. In addition, a scan of the optical density shows the distribution of the total DNA in the gradient. A significant shoulder appears on each side of the main band of DNA. The component with the highest density contains a significant amount of ¹⁴C-bromouracil, and there is a detectable amount of bromouracil in the light fraction. Previous studies have revealed that when the highdensity satellite is rebanded it again occupies the same density position in the gradient (Miner, 1967). The light component is more difficult to follow, and its rebanding properties and composition are still in doubt. Shearing the heavy satellite breaks out segments which appear to be fully substituted with bromouracil as shown in Figure 12 (Miner, 1967; Taylor and Miner, 1968). The original distribution of DNA (Figure 12A) shows clearly a labeled heavy satellite on the left of the main band as well as a very slightly labeled light satellite on the right. The hybrid density band is shown distinctly at the far left. Rebanding one-half of the unsheared DNA in fractions 40 to 42 (Figure 12A) indicates that the satellite is a distinct fraction that maintains its density upon

FIGURE 11 Profile of DNA in a CsCl gradient produced by spinning DNA in a Spinco SW 39 rotor for 48 hours. The DNA was extracted from hamster cells after they grew for four hours in a medium containing ¹⁴C-bromodeoxyuridine which substituted for thymidine. Thymidylate synthesis was blocked by fluorodeoxyuridine (10^{-6} M). The position of the bands of DNA is indicated by the variation in optical density (open circles), and the density hybrid is also indicated by the radioactivity (closed circles). Note the atypical shoulders on each side of the main band of DNA which in less steep gradients are resolved into satellite bands. (From Miner, 1967.)

FIGURE 12 Profiles of hamster DNA in CsCl gradients after four hours of replication in which substitution of bromodeoxyuridine for thymidine occurred after a period of one hour in which replication was blocked with FUdR. A. The original profile of the chromosomal DNA, showing the density hybrid as a heavy satellite to the left of the main band. B. Rebanding of fractions 40–42 with unlabeled marker DNA without shearing. C. Rebanding of a portion of the same fractions sheared to a molecular weight of about 10^6 daltons along with unlabeled DNA which was not sheared. (From Miner, 1967.)

rebanding (Figure 12B). After shearing, however, this same DNA can be demonstrated to contain short segments with enough bromouracil to make the average density nearly as high as the regular density hybrid (Figure 12C).

We originally interpreted the satellite as an indication of interrupted growth because of these properties and because such a satellite does not occur during replication of DNA with thymidine instead of bromodeoxyuridine (Taylor and Miner, 1968). Now we can think of the interruption in terms of the new model of replication (Figures 8 and 9). If one strand of each A-T segment in the DNA were predominantly adenine and the other segment predominantly thymine, the peculiar satellites could be explained. Let us assume that the segment with the high adenine content alternates in a regular sequence with the high-thymine segment, as shown in Figure 13A. If initiation is restricted to one strand of each A-T segment and occurs at opposite ends of each 2-micron subunit, a sequence of 2-micron subunits will have either the A strands or the T strands replicated, but not both. Those regions with replicated T strands would be heavily substituted with bromouracil in short segments and would band as a heavy satellite. The regions with replicated A strands would be light and would contain a small amount of 14C-bromouracil either if random breaks isolated single T segments with a group of adenine-containing regions, or

FIGURE 13 Diagram of segments of DNA showing possible initiation of replication at the 0 segments with various arrangements of these high A-T segments. A. Alternating adenine- and thymine-rich segments along a polynucleotide chain with all partial replicas composed of thymine-rich segments. B. All the thymine segments in one chain but with alternate initiation of thymine- or adenine-rich segments. C. Mixed A-T polymer in each segment along the polynucleotide chains. Note that if alternate sites along a chain are initiated, the structure will remain intact. A, B, and C show various extreme arrangements of nucleotides. Probably no DNA reaches any of these extreme compositions, but, if species variability in these segments is high, all three situations might be approached by some organisms.

if the high-A strands contained a small amount of bromouracil, which would substitute for a naturally occurring thymine in the predominantly A segment. The assumption is made that the partially replicated segments form a rather stable three-stranded region (Syzbalski, 1969), which behaves in a way similar to native DNA in a solution of CsCl.

If the hypothesis is correct, the light satellite should disappear after replication is complete, but the heavy satellite should persist because of its bromouracil content. Figure 14 presents an example that shows the survival of the heavy satellite through a division stage before which all DNA may be assumed to have completed replication. The DNA was labeled with ¹⁴C-thymidine over a long period to get essentially uniform label in chromosomal DNA. Then a portion of the replicating DNA was labeled with nonradioactive bromouracil by growing cells in the corresponding nucleoside for three hours along with FUdR to block thymidylate synthesis. By removal of FUdR, cells were then allowed to

FIGURE 14 Profile of DNA in a CsCl gradient which was labeled rather uniformly with ¹⁴C-thymidine and then, during the late part of a subsequent S phase, was forced to incorporate the density label, bromodeoxyuridine. Cells were collected at the following metaphase, and further synchrony in entering the next S phase was induced by FUdR given during the last four hours of G1. Release of the cells into the S phase with ³H-thymidine allowed the new DNA to be seen in the gradient. The point of interest here is the observation that during bromodeoxyuridine incorporation a density hybrid was formed, as well as a heavy satellite band, which shows a rather narrow distribution in the gradient in spite of the fact that random shearing of the DNA reduced the particle weight to 5-10 imes 10⁶ daltons before banding. In spite of considerable variation in length of DNA particles, the ratio of bromouracil to thymine in the partial replicas is remarkably uniform.

recover the ability to make their own thymidylate. Cells labeled in this way were collected by shaking them off the glass surface at metaphase; they then were allowed to proceed synchronously to the S phase. Synchrony was increased by treatment with FUdR during the last four hours of the G₁ phase. Note that the heavy satellite persists and replicates without changing its density. The density of this heavy satellite is about one-third of that of the density hybrid, which is fully substituted in one strand. If the T segments alternated with A segments, as shown in Figure 13A, they could be fully substituted and, after replication, would represent one-third of the thymine in one polynucleotide chain of each DNA duplex. This would be consistent with the density position of the satellite band in Figure 14.

The density of partially substituted DNAs before replication is completed would be difficult to predict because not only is the pairing of the third strand uncertain; the proportion of the partially replicated sites might vary. The observation is that satellites of variable densities are found. Very short periods of substitution produce only a small change in density-about 15 per cent (Taylor and Miner, 1968)-but, after longer periods of substitution, the density of the satellite increases to one-third or one-half of that of hybrid DNA and finally merges with the hybrid band when bromodeoxyuridine remains available to the cell to complete replication. Figures 15 to 17 show three stages in the replication of DNA with bromouracil substituted for thymidine. Cells were prelabeled with 14C- and then 3Hthymidine for part of one S phase. They were then synchronized by shaking off metaphases and treating them with FUdR during the last four hours of G1. Release of the cells into S phase with bromodeoxyuridine allowed replication. Some partial replicas, however, are indicated by the heavy satellite that appeared after one hour (Figure 15). Its density indicates substitution to the equivalent of about one-third or less of the thymine in one strand. After three hours (Figure 16), the average density indicates the equivalent of one-half substitution in one strand. By five hours, all the partially replicated DNA had become hybrid, with one strand fully substituted (Figure 17).

The partial replicas are consistent with our model of replication, and their presence is explained by the model, but of course such data can never prove the correctness of the model. Other more direct proof and evidence for or against the model are being assembled and, we hope, can be presented in a few months.

The partial replicas almost certainly exist, even if the model is incorrect. Their existence under these rather unusual conditions of replication might be less important if they did not occur under conditions that the cell probably meets during its normal replication and growth. Some evidence suggests that such partial replicas can be induced by perturbing DNA replication in other ways. If these partial replicas can be shown to be induced in cells at certain stages or to happen regularly during replication, they certainly provide the raw materials for various types of recombination between chromosomes. Some of the recombination in phages appears to be associated with partial replicas of the whole genome. As was pointed out previously, such partial replicas of DNA subunits in the chromosome provide a

FIGURE 15 Profile of Chinese hamster DNA in a CsCl gradient with a uniform label of ¹⁴C-thymidine and a part of an S phase in ³H-thymidine followed by synchronization and incorporation of the density label, bromodeoxyuridine, for one hour. Notice that the heavy satellite constitutes a significant proportion of the total DNA.

FIGURE 16 Profile of DNA in a CsCl gradient similar to that in Figure 15 except that the incorporation of bromodeoxyuridine continued for three hours. Note that the heavy satellite is now of a higher density, nearly one-half substituted compared with the hybrid band.

FIGURE 17 Profile of another sample of DNA similar to that in Figure 15, except that incorporation of bromodeoxyuridine had continued for five hours, and all the DNA has replicated that would do so under these conditions of growth. Note that the heavy satellite has disappeared, presumably because it had finally become fully substituted hybrid DNA.

means for nonreciprocal recombination (Taylor, 1967) as well as associated events that could lead to reciprocal recombination without loss of viability of either of the four chromatids of the two chromosomes involved.

Although the regulation of replication and transcription is not evident either from the proposed model of DNA or from its mechanism of replication, several possibilities are presented. One level might be the role of some nuclease that opens the 2-micron subunit by nicking one strand. Another is possibly the regulation of initiator-primer production. If the hypothesis presented is correct, replication of DNA follows a scheme similar to that indicated for RNA, coli phage ϕX DNA, and other systems in which a threestranded intermediate is believed to exist during replication. A difference between the RNA and DNA systems would be the requirement for a primer (short-chain initiators) in DNA replication, but this could have evolved as a mechanism that preserves a necessary structural irregularity in DNA that could not be copied by the regular base-pairing mechanism. We have suggested mismatched base pairs as the structural basis for the flexible joints, but this is only one possibility. The basis for flexible joints can be decided only when the base composition and sequence in the initiators are known and their role in replication is confirmed.

The role of proteins in chromosomal organization and regulation

The histones form complexes with DNA in vitro and presumably have some resemblance to the complexes that exist in the intact cell. Bonner et al. (1968) and Georgiev (1968) have shown that histone I is removed completely by 0.6 mmm NaCl, but the other known classes of histones are not removed so readily. However, higher salt concentrations completely remove histones from DNA and there are probably no covalent linkages between the two molecular species. Bonner's group (1968) has identified a small RNA molecule that is believed to be linked to a nonhistone protein. The histones are thought to form a complex with this protein. Their suggestion is that the RNA finds a complementary site on the DNA and thereby guides the positioning of the histones on the DNA. It is interesting that our presumed initiator DNA is about the same size as this RNA.

Histone I is easily removed by low salt concentrations, and also has some interesting properties with respect to maintenance of the structure of the 230-Å fibril and the regulation of RNA transcription. According to Bonner et al. (1968), the histones will reassociate with the DNA in what they believe to be the native nucleohistone state. This blocks the transcription of RNA. Furthermore, removal of the histone allows synthesis of RNAs that have a high affinity for the DNA in molecular hybridization tests. Georgiev (1968) reported, however, that the removal of only the histone I from DNA gives maximum synthesis of this type of RNA. Replacement of histone I prevents this synthesis by RNA polymerase, although Georgiev does not agree that it restores nucleoprotein to its original native state. He also pointed out that removal of histone I causes the nucleoprotein fibrils to unfold and be reduced in diameter to about 40 Å.

These findings lead us to suggest that histone I is complexed to the A-T segments in our model of the chromosomal DNA. It is primarily the copying of these segments by RNA polymerase that yields the RNA with a high affinity for DNA, as suggested by Georgiev. Such RNA should have a high uracil content similar to or higher than certain nuclear RNAs. That is not to say that other segments would not be copied to some extent, but the RNA from other segments should have a low affinity in the hybridization tests. Flamm et al. (1969) reported that messenger RNA (cytoplasmic RNAs, other than ribosomal, that have high molecular weight) do not bind to the light-satellite DNA of the mouse, which has a high content of A-T (66–67 per cent). We propose that the light-satellite DNA in most, if not all, cases contains two 0.4-micron segments of A-T DNA for each four heterogeneous segments in contrast to main-band DNA, which, we think, contains one A-T segment per four segments of heterogeneous base composition (nearly equimolar ratios of A + T and G + C). The base composition of mouse satellite reported by Flamm et al. (1969) is consistent with this hypothesis, for the percentage

of G-C in the satellite is 33.3 per cent rather than the 40 per cent characteristic of main-band DNA.

The addition of these extra segments could be by intercalation or, possibly, by addition of segments as shown in partially replicated DNA (Figure 10). Such segments of DNA either would not be transcribed as a part of messenger RNA or, if transcribed, would be split off before delivery of this RNA to the cytoplasm. On the other hand, the heterogeneous nuclear RNA (Darnell, 1968) would contain copies of these repeating high A-T segments. This would explain its high affinity for DNA in molecular hybridization tests and its high content of uracil.

Recombination and correction mechanisms

A mechanism of recombination based on the pairing of incompletely replicated DNA subunits in chromosomes has been proposed by Taylor (1967). At that time no unit of the size proposed (about 2 microns) was known. Now, with the discovery of a unit of replication of an appropriate size and the usefulness of the model to explain nonreciprocal recombination in ascomycetes (Herbert Gutes, personal communication), the model promises to become a reality instead of a speculative scheme. The block in synthesis could occur after the synthesis of the A-T segments or some other portion of 2-micron units. Less frequently, a three-stranded region would be formed by the growth of one strand of a 2-micron subunit, but the other strand would be blocked after the formation of the A-T segment only. The threestranded segments in two homologous chromosomes would be the basis for nonreciprocal recombination in which segregation is in the ratio of 3:1 or 6:2. The A-T segments, which should be the most common type of interrupted chain growth, could also provide a mechanism for specific pairing, if the assumption is made that base sequence of these subunits varies along the chromosome in rather subtle ways. Their similarity could provide a mechanism of nonhomologous and homologous pairing when the exact partner was absent, as in haploids, some hybrids, and allopolyploids. Considerably more information on the similarity of the A-T segments within and between phylogenetically related genomes is necessary before valid predictions can be made.

The work of Waring and Britten (1966) and Flamm et al. (1969) indicates that many similar sequences occur in each complement, but the degree of similarity is not clear. Are they exact copies and, if so, what mechanism keeps them similar or identical within a species? The persistence of multiple copies of any locus implies some kind of correction mechanism. We have few clues as to how this correction operates. An internal recombination system that continually produces exchanges of A-T segments between different parts of the genome does not appear very attractive. A periodic replacement of the segments from some limited number of copies at certain stages of the life cycle, at meiosis, or in early embryonic development is an interesting possibility. Another plausible, but unorthodox, possibility is the production of RNA by transcription of a master DNA copy. By excision and replacement of mismatched base pairs similar to DNA repair replication, DNA chains, rather than RNA chains, might be altered selectively. Such a mechanism might provide a role for the heterogeneous nuclear RNA that appears to have such a high turnover and never to leave the nucleus, but any precise scheme is too speculative now to merit recording. Nevertheless, the role of RNA in transformation or modification of DNA in higher cells should not be dismissed too lightly. Admittedly, the evidence so far presented is only suggestive, but better-designed experiments are called for. A case in point is the report of Temin (1964) that the nucleotide sequences of viral RNA in Rous sarcoma are found in the DNA of transformed cells. If the transfer can be demonstrated in one clear case, the way would be open for an understanding of many puzzling phenomena relating to long-lasting immunity and, perhaps, to long-term memory mechanisms.

Transcription and differentiation of neuronal nets

One of the most interesting and provocative reports on nucleic acids, and one that may have significance for memory mechanisms, is that which indicates that some cell membranes may contain RNA and, furthermore, that this RNA may extend out and make contact with the environment of the cell and its neighbors. Mayhew and Weiss (1968) have reported that cells have negative surface charges that affect their electrophoretic mobilities. The charge is changed when the cells are placed in ribonuclease; this suggests that RNA which extends out from the membrane is removed. Furthermore, cells in culture that are attached to glass or plastic surfaces leave radioactive "footprints" if the RNA is labeled with ³H-uridine (Weiss and Mayhew, 1966). Although these bits of evidence cannot be taken as conclusive, the possibility that RNA is found in plasma membranes raises some interesting questions. Could such RNA be the basis for cell-to-cell contact specificity in differentiation? We need only imagine that cells of a particular type produce copies of an RNA, which becomes attached to a structural component of the membrane so that chains extend out and form base pairs with complementary chains from another cell that is an acceptable associate. Cells without complementary sequences would not be accepted. One mechanism to insure complementarity would be a cell programed to transcribe the plus strand at a DNA locus while its sister cell would be programed to transcribe the minus strand at the same locus. If there were several independent loci, a high degree of specificity could be attained by the appropriate regulation of such a genetic system.

If specific RNAs at surfaces were a property of cells in which a mechanism of differentiation has evolved, it would be easy to see how the system could be specialized for neuronal recognition. The puzzling recognition system that optic nerve axons have for their specific neurons in the optic tectum of the frog (Sperry, 1951) could have such a basis. The specificity of such a recognition system could be subtle and precise, and the variability could be sufficient for an almost infinite number of pair recognitions. The proper regulation in such a system could give a large population of interacting cells or only pair mates. If the locus held in common were fixed at the division from which two daughters were produced, these would be the only two to interact.

Such mechanisms could be extended to explain the inheritance of neural nets that predetermine certain behavior patterns or instinctual behavior in animals. The mechanism would require precise regulation associated with segregation of the genome during critical cell divisions in which pairs or more complex associations of sensory and motor neurons were being produced. Speculation on precise regulatory mechanisms that could achieve such patterns, however, would not appear to be fruitful without some evidence that properties of RNA in cell surfaces and in junctions of the type involved actually indicate determination of specificity. The challenging problem is to devise experiments that could yield further clues concerning the existence of this type of RNA.

If long-term memory involves the change in any molecule, and one must assume it does, the record of the change would almost have to be recorded in a nucleic acid, and chromosomal DNA is probably the best candidate. The easiest change to imagine would be one that alters an RNA molecule, not in such a way as to code a message or bit of information directly, but in such a way as to alter the future behavior of the cell, perhaps in a way that would change the spike-train pattern in a subtle way or alter its responsiveness to an impulse of a particular type, frequency, or magnitude. We believe the most plausible feedback to the chromosomal DNA would be through an RNA that could transform a specific locus which originally produced it. This would have to be done in such a way that molecules of RNA identical to the one effecting transformation would be transcribed from the locus thereafter. These statements are made with the full knowledge that molecular biologists have not discovered such mechanisms and are not likely to until higher cells can be studied by rigorous genetic and chemical techniques that have been successful in demonstrating DNA

transformation in bacteria with DNAs of viral and bacterial origin.

Acknowledgment

We wish to acknowledge the contribution of unpublished data obtained in our laboratory by Dr. Philip Miner (Figures 10 and 11) and by Dr. Terry L. Myers (Figures 13–16), and to thank Mrs. Nancy Straubing for her technical assistance. The experimental work was supported by Contract AT(401–1)2690 with the Division of Biology and Medicine, U. S. Atomic Energy Commission, and by National Science Foundation Grant GB-6568.

- LANGE, G. DAVID Assistant Professor of Neurosciences, University of California at San Diego School of Medicine, La Jolla, California 92037
- LEHNINGER, ALBERT L. Professor and Director of the Department of Physiological Chemistry, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205
- LENNEBERG, ERIC H. Professor of Psychology and Neurobiology, Department of Psychology, Cornell University, Ithaca, New York 14850
- LEWIS, EDWIN R. Associate Professor, Department of Electrical Engineering and Computer Sciences, University of California at Berkeley, Berkeley, California 94720
- LIVINGSTON, ROBERT B. Professor and Chairman, Neurosciences Department, University of California at San Diego School of Medicine, La Jolla, California 92037
- LLINÁS, RODOLFO Division of Neurobiology, Department of Physiology and Biophysics, University of Iowa, Oakdale Campus, Iowa City, Iowa 52240
- LYSER, KATHERINE M. Associate Professor, Department of Biological Sciences, Hunter College of the City University of New York, New York, New York 10021
- McConnell, Harden M. Professor of Chemistry, Stanford University, Stanford, California 94305
- MACKAY, DONALD M. Professor of Communications, University of Keele, Keele, England
- MACLEAN, PAUL D. Chief, Section on Limbic Integration and Behavior, Laboratory of Neurophysiology, National Institute of Mental Health, National Institutes of Health, Bethesda, Maryland 20014
- MALETTA, GABE J. Staff Physiologist and Health Scientist Administrator, Adult Development and Aging Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20014

- MARCHALONIS, JOHN J. Assistant Professor of Medical Sciences, Brown University, Providence, Rhode Island 02912
- MELNECHUK, THEODORE Director of Communications, Neurosciences Research Program, Massachusetts Institute of Technology, Brookline, Massachusetts 02146
- MORRELL, FRANK Brain Research Laboratory, Department of Psychiatry, New York Medical College, Fifth Avenue and 105th Street, New York, New York 10029
- MÜLLER, EUGENIO E. Associate Professor of Pharmacology, Istituto di Farmacological di Terapia, Universita Degli Studi, Via Vanvitelli 32, 20129 Milan, Italy
- MURPHY, JOHN T. Assistant Research Professor of Physiology, State University of New York at Buffalo, Buffalo, New York 14226
- NAUTA, WALLE J. H. Professor of Neuroanatomy, Psychology Department, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139
- NELSON, PHILLIP GILLARD Chief, Behavioral Biology Branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, Maryland 20014
- NIRENBERG, MARSHALL W. Chief, Laboratory of Biochemical Genetics, National Heart Institute, National Institutes of Health, Bethesda, Maryland 20014
- NOMURA, MASAYASU Professor of Genetics, University of Wisconsin, Madison, Wisconsin 53706
- NORTON, ALLEN C. Assistant Professor of Physiology, Brain Information Service, University of California, The Center for Health Sciences, Los Angeles, California 90024
- NOTTEBOHM, FERNANDO Assistant Professor, The Rockefeller University, New York, New York 10021
- OLIVERIO, ALBERTO Laboratory of Psychobiology and Psychopharmacology, Consiglio Naxionale delle Ricerche, Via Reno 1, 00198 Rome, Italy
- ONSAGER, LARS J. W. Gibbs Professor of Theoretical Chemistry, Yale University, New Haven, Connecticut 06520
- OSHIMA, TOMOKAZU Department of Physiology, Toho University School of Medicine, 5–21 Omori-Nishi, OTA-Ku, Tokyo, Japan
- PARTLOW, LESTER MARTIN Postdoctoral Fellow, Department of Biology, The Johns Hopkins University, Baltimore, Maryland 21218
- PERKEL, DONALD H. Department of Biological Sciences, Stanford University, Stanford, California 94305
- PFAFF, DONALD Assistant Professor, Biomedical Division of the Population Council, The Rockefeller University, New York, New York 10021
- PFEIFFER, STEVEN E. Postdoctoral Fellow, Graduate Department of Biochemistry, Brandeis University, Waltham, Massachusetts 02154
- PFENNINGER, KARL H. Research Associate, Brain Research Institute, University of Zurich, 8008 Zurich, Switzerland
- PLOOG, DETLEV Professor of Psychiatry, Max Planck Institute for Psychiatry, 8 Munich 23, Germany

- PRESTIGE, MARTIN C. Lecturer in Physiology, University of Edinburgh, Edinburgh, 8, Scotland
- PURPURA, DOMINICK P. Professor and Chairman, Department of Anatomy, Albert Einstein College of Medicine, Bronx, New York 10061
- QUARTON, GARDNER C. Director, Mental Health Research Institute, University of Michigan, Ann Arbor, Michigan 48104
- RALL, WILFRID Senior Research Physicist, Mathematical Research Branch, National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda, Maryland 20014
- REDMAN, STEPHEN JOHN Department of Electrical Engineering, Monash University, Clayton, Victoria 3186, Australia
- REICHARDT, WERNER E. Professor and Director, Max Planck Institute for Biological Cybernetics, 7400 Tübingen, Germany
- RICHARDS, FREDERIC M. Ford Professor of Molecular Biophysics, Yale University, New Haven, Connecticut 06520
- ROBERTSON, J. DAVID Professor and Chairman, Anatomy Department, Duke University, Durham, North Carolina 27706
- ROSENHECK, KURT Polymer Department, Weizmann Institute of Science, Rehovoth, Israel
- SAMSON, FREDERICK E., JR. Professor and Chairman, Bureau of Child Research and Department of Physiology and Cell Biology, University of Kansas, Lawrence, Kansas 66044
- SCHARRER, BERTA Professor of Anatomy, Albert Einstein College of Medicine, Bronx, New York 10461
- SCHEIBEL, ARNOLD B. Associate Professor of Anatomy and Psychiatry, University of California Medical Center, Los Angeles, California 90024
- SCHEIBEL, MADGE E. Associate Professor of Anatomy and Psychiatry, University of California Medical Center, Los Angeles, California 90024
- SCHMITT, FRANCIS O. Institute Professor, Professor of Biology, Chairman, Neurosciences Research Program, Massachusetts Institute of Technology, 280 Newton Street, Brookline, Massachusetts 02146
- SCHMITT, OTTO H. Professor of Biophysics-Bioengineering, Department of Electrical Engineering, Institute of Technology, University of Minnesota, Minneapolis, Minnesota 55414
- SCHNEIDER, DIETRICH Director, Max Planck Institute for Behavioral Physiology, Seewiesen über Starnberg, Germany
- SCHNEIDER, GERALD E. Assistant Professor, Department of Psychology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139
- SEGUNDO, JOSÉ, P. Professor of Anatomy, University of California, Los Angeles, California 90024
- SHAW, LESLIE M. J. Postdoctoral Fellow, Mergenthaler Laboratory for Biology, The Johns Hopkins University, Baltimore, Maryland 21218
- SHELANSKI, MICHAEL L. Assistant Professor of Neuropathology, Albert Einstein College of Medicine, Bronx, New York 10461
- SHEPHERD, GORDON M. Assistant Professor, Department of

Physiology, Yale University School of Medicine, New Haven, Connecticut 06520

- SHOFER, ROBERT J. Assistant Professor, Department of Anatomy, Albert Einstein College of Medicine, Bronx, New York 10461
- SHOOTER, ERIC M. Professor of Genetics and Biochemistry, Department of Genetics, Stanford University School of Medicine, Stanford, California 94304
- SIDMAN, RICHARD LEON Professor of Neuropathology, Harvard Medical School, Boston, Massachusetts 02115
- SINSHEIMER, ROBERT L. Chairman, Division of Biology, California Institute of Technology, Pasadena, California 91109
- SIZER, IRWIN W. Dean of the Graduate School, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139
- SMITH, ANDREW P. Graduate Student, Department of Genetics, Stanford Medical Center, Stanford, California 94305
- SMITH, BARRY HAMILTON Rogosin Laboratories, Cornell University Medical College, 525 East 68th Street, New York, New York 10021
- SPIEGELMAN, SOL Director, Institute of Cancer Research, Columbia University, New York, New York 10032
- SPOONER, CHARLES E. Assistant Professor of Neurosciences, University of California at San Diego School of Medicine, La Jolla, California 92037
- STEIN, RICHARD B. Associate Professor, Department of Physiology, University of Alberta, Edmonton, Alberta, Canada
- STENT, GUNTHER S. Laboratory of Neurobiology, Harvard Medical School, 25 Shattuck Street, Boston, Massachusetts 02115
- STONE, FREDERICK L. President, New York Medical College, Flower and Fifth Avenue Hospital, New York, New York 10029
- SWEET, WILLIAM H. Chief, Neurosurgical Services, Massachusetts General Hospital, Professor of Surgery, Harvard Medical School, Boston, Massachusetts 02114
- SZENTÁGOTHAI, JOHN Professor and Director, Department of Anatomy, University Medical School, Budapest IX, Hungary
- TAYLOR, J. HERBERT Professor, Institute of Molecular Biophysics, Florida State University, Tallahassee, Florida 32306
- TAYLOR, WILLIAM M. Research Training Grants Branch, National Institute of General Medical Sciences, National Institutes of Health, Bethesda, Maryland 20014
- TERZUOLO, CARLO A. Professor and Director, Laboratory of Neurophysiology, University of Minnesota Medical School, Minneapolis, Minnesota 55455
- THOMAS, CHARLES A., JR. Professor of Biological Chemistry, Harvard Medical School, Boston, Massachusetts 02115
- VALENSTEIN, ELLIOT S. Senior Research Associate, Professor of Psychology, Fels Research Institute, Antioch College, Yellow Springs, Ohio 45387
- VARON, SILVIO Associate Professor, Department of Biology, University of California at San Diego, La Jolla, California 92037

- VAUGHN, JAMES E. Assistant Professor, Department of Anatomy, Boston University School of Medicine, Boston, Massachusetts 02118
- VIDAL, JACQUES J. Associate Professor, Department of Engineering, University of California, Los Angeles, California 90024
- WALLØE, LARS Lecturer, Institute of Physiology, Oslo University, Oslo 1, Norway
- WANG, HOWARD Assistant Professor, Division of Natural Sciences, University of California, Santa Cruz, California 95060
- WASHBURN, SHERWOOD L. Professor of Anthropology, University of California, Berkeley, California 94720
- WECHSLER, WOLFGANG Max Planck Institute for Brain Research, Ostmerheimer Strasse 200, 5 Koln-Merheim, Germany
- WEISS, PAUL A. Professor Emeritus, The Rockefeller University, New York, New York 10021
- WERNER, GERHARD Professor and Chairman, Department of

Pharmacology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania 15213

- WHITTAKER, VICTOR P. Professor, Department of Biochemistry, University of Cambridge, Cambridge, England
- WILLIAMS, HAROLD L. Research Professor of Psychology, Department of Psychiatry and Behavioral Sciences, University of Oklahoma School of Medicine, Oklahoma City, Oklahoma 73104
- WILSON, DONALD M. Professor of Biology, Stanford University, Stanford, California 94304
- WORDEN, FREDERIC G. Executive Director, Neurosciences Research Program; Professor of Psychiatry, Massachusetts Institute of Technology, Brookline, Massachusetts 02146
- WURTMAN, RICHARD J. Professor, Department of Nutrition and Food Sciences, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

SUBJECT INDEX

Page references to figures and tables appear in italics

А

Acetabularia protein synthesis in, 841, 842 acetoxycycloheximide glycoprotein and, 751, 753, 753 memory, effect on, 272-273, 272, 273, 275 protein synthesis inhibition by, 272ff, 272 acetylcholine, 531, 770ff, 770 biosynthetic pathway, 772 insect nervous system, effects in, 792 localization, 764-765, 771 metabolism, drugs and, 340 miniature endplate potential and, 715, 774 muscle fiber sensitivity to, 776 as neurotransmitter, 329 in synaptic vesicles, 722-723, 725, 771 acetylcholinesterase colchicine blocking of, 846, 848 localization, 765-766 actinomycin memory impairment effects, 275, 275 RNA synthesis, effect on, 275 ACTH (adrenocorticotropic hormone) effect on PNMT activity, 533 localization of, 764ff, 765 in mammalian adrenal medulla, 533, 533 subcellular and released, 765 action potential mechanism for, 858-859 of nerve tissue in vitro, 89, 94 neuronal, extracellular recording, 649 neuronal, intracellular recording, 648-649 prolongation, 707, 707 activating system nonspecific, 377 adaptive behavior, 188 affective state, role in forming, 330 of birds, 41-42 genetic influences, 192ff innate and learned responses, 193-194 phylogenetic selection pressures and, 194 of primates, 42ff protracted parental care and, 194 of rats, 42 reinforcing events, 193 ritualization as, 350 stimulus significance and, 330 adenohypophysis, 525 neurosecretomotor junctions in, 523 adenyl cyclase, 535 function, 871, 872 ADP (adenosine diphosphate) transport across mitochondrial membrane, 830-831 see also oxidative phosphorylation ATP (adenosine triphosphate), 830ff as energy source, 828 in mitochondria, 828ff adrenal medulla ATP release during stimulation, 775, 775 catecholamine secretion, 775, 775 chromaffin cells in, 532, 533 chromogranin A release, 775, 775

derivation from neural crest, 62 exocytosis in, 775-776 as a neuroendocrine transducer, 533 adrenalin, 770 adrenomedullary chromaffin cells, 530 affect, 324, 337-338, 338, 341 adaptive behavior, role in, 330 amine roles, 324ff, 332 behaviors guided by, 338 brain correlates, 302 brain mechanisms, 344-345 defined, 337 during epileptic seizure, 341ff humoral and neural mediation, 331 individuality and, 346 limbic system role, 302 norephinephrine role, 327 schematic view of, 338 self-orienting nature of, 346 see also emotion; individuality, sense of afterimages, 306, 307 complementary images, 307 waterfall effect, 308 see also optical illusions afternystagmus, 264-265, 265, 266 aggregation culture, 105-106, 105 aldosterone binding to specific nuclear protein, 823 see also hormones alga, see Acetabularia alkali ion ligand binding and, 685ff, 685, 686 alkali-ion carrier complexes, 693-696 equilibration, 689ff macrotetrolide, structure, 691, 692 stability constants, 685-686, 686, 687 alkali-ion carriers, 685-696 allelic exclusion, 893 alligator parallel fiber activation, 420 allocortex neurogenesis, 65, 68 see also isocortex amacrine cells, 563 see also axonless cell; granule cell amines appetitive behavior, role in, 328, 329 biogenic, 324-336 emotion, role in, 324 learning, role in, 330ff, 332 memory, role in, 329-330 metabolism, drugs and, 340 neurotransmitters in brain, 327 in non-neuronal tissues, 771 see also catecholamine; dopamine; epinephrine; norepinephrine amino acid sequences of light chains of protein Eu, 889, 889, 891, 892, 895 C region, 890ff V region, 890ff, 893 amnesia, anterograde, 164, 168, 169, 173 classical conditioning in, 170

due to Papez circuit lesions, 172

primary memory in, 169 secondary memory in, 169 sensory memory in, 169 amnesia, retrograde, 164, 171, 172, 173, 273-274 electroconvulsive shock effects, 273-274 primary memory in, 171 puromycin and, 275 secondary memory in, 171 tertiary memory in, 167, 171 AMP (adenosine monophosphate), cyclic function, 330, 871-872, 872 norepinephrine, effects on, 333 amphetamine memory, effects on, 273, 273 amphibians motor system organization, 109 optic nerve regeneration, 154 phylogeny, 28-29, 29 see also frog; salamander; toad; urodeles amputation, larval limb effect on peripheral nervous system, 76ff effect on ventral-horn cells, 76, 78, 78 amygdala, 464, 465 androgen alteration of nerve tissue hormone sensitivity, 201, 205 central nervous system action, 294 male social behavior and, 201-205, 202, 203 see also testosterone androstenedione, 200 see also androgen; testosterone animal behavior social communication, 349-359 stereotypic, 291, 339 see also adaptive behavior; comparative psychology; ethology annealing of polynucleotide chains, 951, 988, 989, 991 ANS (1-anilino-8-naphthalenesulfonic acid), 834 ansa lenticularis, 465, 466, 466, 467 anterograde amnesia, see amnesia, anterograde antibiotics complex formation constants, 685-686, 686 effects on ribosome, 923, 923 "hole punchers," 682 ion-selective, 685, 685 ionophorous, 831 ligand role in complex formation, 686-687 mitochondrial membrane permeability, effect on. 831 antibodies, 882-900 complementarity with hapten antigen, 886 constant regions, 889, 890, 893 degenerate response of, 886-887 diversity of, 889ff domain hypothesis, 896 eukaryotic differentiation and, 898 evolution, 893, 894, 895, 896 gamma globulin, 962-963, 969 genetics of, 885-900 heterogeneity of, 887

motor skills in, 169, 170

operant conditioning in, 171

perceptual learning in, 171

homology, 894, 894, 895 multiple genes and, 897, 897 origins of diversity, 890-893, 893 protein specificity and, 885 production of, 885-886 response to antigen, 886, 887 structure of, 885-900 synthesis, 887ff translocation, 893 variability, 968 variable regions, 889-894 see also antigens; immunoglobulin antidromic activation of mitral cells, simulated, 554-555, 557, 558, 558 antigens antibody response to, 886 binding functions, 886, 887, 893, 894 effector functions, 887, 893, 894, 896 neuroglial, 279ff, 280, 281 neuronal, 279ff, 280, 281 recognition, 887 specificity and range in binding, 886, 886, 887 structure, 887 apes (Pongidae) phylogeny, 43 social behavior, 43 vocal repertoire, 352 see also chimpanzee; gibbon; primates aphasia cerebral dominance and, 362 clinical symptoms, 363 cognitive disorders and, 366 etiology, 367 handedness and, 362 symptom classification, 363, 364 symptom dissociability, 364-365, 364 see also language disorders Aplysia heterosynaptic facilitation in, 263 neuron plastic properties, 266-267, 268, 269 rhythm assimilation by, 266-267, 268, 269 appetitive behavior, 330 amine role in, 328, 329 dopamine effect on, 329 genetically significant stimuli and, 330 norepinephrine-induced, 329 plasticity, 291 archenteron, 62 area dentata neurogenesis, 65, 67 arousal adaptive learning and, 331 biogenic amines and, 324-336 memory, role in, 273 norepinephrine role, 329 arthropods neurons, 399-402, 401-403 pattern generators, 399-408 astrocytes, 792, 793, 795 ATP (adenosine triphosphate) release, 775 synthesis, 681 transport across mitochondrial membrane, 830-831 see also oxidative phosphorylation auditory perception of blind persons, 314 contrast enhancement, 304 see also speech perception auditory system, 14

avian, 22, 23 thalamic representation, 14 aura, 342 see also epilepsy Australopithecus, 40 hand features, 44 autonomic nervous system operant conditioning of, 218-222 plasticity in, 218-223 autoradiography, 64, 1005 cell counts by, 74 cell migration, 74, 103 cell proliferation, 63, 64 optic vesicle, 122 peripheral neuron sheath derivations, 62 regional analysis by, 64 see also radioisotopic analysis avian brain, 10ff auditory structures, 22, 23 acetylcholinesterase in, 20, 20 cerebral hemisphere, 12 morphology, 15, 20-24 quinto-frontal tract, 14 thalamus, 15-16 visual system, 20-22, 22 vs. mammalian brain, 24 Wulst region, 16, 21, 25 see also external striatum avoidance behavior, conditioned, 328, 330 axolemma myelin contacts with, 787, 788 nerve-fiber membrane fluidity and, 701 axon branching patterns, 860 degeneration, 806, 809 dispersion of labeled protein in, 851-852, 851, 852 filtering of spike train patterns, 377 formation, 70 fusion, in silk moth antenna, 513 growth, 125, 126 myelinated, 790 nourishment by myelin sheath, 791 pathways, establishment of, 111-112 protein synthesis, 815, 843-844 regeneration, 801, 802, 806, 808, 810 Schwann cell, role in outgrowth, 112 'specific and nonspecific afferents", 331, 333 see also myelin sheath; nerve fiber; nerve fiber connections; Schwann cells axon terminals in cerebella glomeruli, 427 of Golgi cells, 427, 429 in LGB glomeruli, 431, 433 in VPL glomeruli, 433 axonal arbors, 444, 446 high-fidelity transmission in, 444, 446 high-priority transmission in, 444 axonal flow, 842ff see also neuroplasmic flow axonless cells, 547, 563 comparison of olfactory bulb and retina, 541, 548, 549, 550 key integrative function for, 547 axoplasm amino-acid composition of fibrous proteins, 855, 855 DPF (di-isopropylphosphorofluoridate) in, 792 ionic composition, 769, 769 neurotransmitter storage and, 773 organic anions in, 768-769, 769

axoplasmic transport, 851-857 bidirectional, 853 chromogranins and, 873 colchicine effects, 851, 852, 855-856 concentration gradient, 852 dispersion of labeled protein, 851-852, 851, 852 experimental parameters, 851-853 functions, 856 laminar flow, 851, 852 localization, 851 mechanisms, 853-856 microtubule role, 854 nerve membrane role in, 833-854 neurofilament role in, 854-855 protein and, 852, 852, 853, 853 speed of, 855-856 temperature dependence, 852 velocities, 852, 855 see also neuroplasmic flow В bacteriophage DNA, 994 RNA replicase, 931, 932, 933 transducing, 958ff, 959

bacteriophage lambda, 946, 949, 950ff

DNA ends, 955, 956, 957, 957

Calliphora, see fly carbohvdrates on cell surfaces, 748, 750 cardiovascular disorders operant conditioning therapy, 218 carrier-complex formation, 693-694 monotonic size dependence, 688 rate constants, 687-688, 688 see also alkali-ion carrier complexes carrier molecule equilibration, 693, 693 metal-ion, efficiency specifications, 694-695 selectivity, 685, 692 see also alkali-ion carrier Casper-Hauser experiment, 192 carotid reflex, 54 cat behavioral studies of, 229-233 EEG analysis of, 230-232 evoked potential in, 250, 251, 253, 254, 255 norepinephrine in, 773 vision studies, 321-322, 322 catecholamine, 324-325, 328 action in periphery, 324-326 appetitive behavior and, 328 biosynthetic pathway, 772 central nervous sytem, distribution in, 327 depletion in brain, 328 distribution, 771 drugs and, 328 fluorescence, 327 storage in synaptic vesicles, 732 in telencephalon, 327 see also dopamine; epinephrine; norepinephrine caudal sensory relay, 444 caudate neurons, 464

cell adhesion, 125-126 cell migration and, 126 specificity of neuronal connections and, 126 cell alignment, 104ff, 106 hippocampal formation, 105, 105 mechanism, 106 cell asynchrony, 76 cell count by autoradiography, 74 by mitosis. 74 of ventral-horn cells, 74ff, 75 cell culture, 74, 83-84 aggregation cultures, 105-106, 105 bioelectric maturation, 89-95 cerebral tissue, embryonic, 94-95, 96 CNS tissue, 94-95 enzymatic dissociation, 85, 87, 92 Feulgen staining, 63 growth cones in, 85 histiotypic aggregation in, 86, 89 mechanical dissociation, 95 mutants, 104-105 monolayer, 86, 95 reaggregation, 105 silver stain, 89, 91 see also culture media; explant culture; nerve tissue culture cell death, 58, 71, 73 function, 79 histogenetic, 79, 109 morphogenetic, 79, 109 ventral-horn cells, 74, 76ff, 77 cell degeneration significance of, 79 cell differentiation, 69-71 ablation effects, 79 independence of neurogenetic events, 69ff of neural nets, 1011, 1012 spinal cord regions, 73 vs proliferation of neurons, 841 cell division, see cell proliferation cell evolution, 930 cell interaction, 100-107 cell membrane, see membranes cell metabolism peripheral influences, 80-81 cell migration, 69, 100-107 cell adhesiveness and, 126 cerebellar granular layer, 103, 103, 105 in cerebral isocortex, 101, 101, 104, 104 in CNS development, 100, 102, 102, 103-104 into ventral horn, 79 neuroblast behavior, 69, 70 process, 103-104 trapezoid nucleus, 103-104 cell proliferation, 62-69, 100-107 autoradiographic analysis, 64 brain components, 65ff, 68, 70 cell death and, 102 control of, 102-103 historical perspective, 62-63 histology of, 63 neural tube, 62-63 neuroglia, 69 patterned, 65ff, 101, 103 rate, 102-103 see also ventricular cell cell shape, 104-105 cell turnover, 76 cell types germ, 962, 968

somatic, 962, 963 central canal ciliary beat in, 58 central nervous system (CNS) aberrations, 58 amines in, 324-336 androgen actions on, 294 cell aggregation patterns in, 106 cell types in, 100ff conduction pathways, 9 cortical system, defined, 539 developing, in mammals, 100-107 electrical activity in, 222 functional operations, 379-382, 381 mammalian, 100-107 morphogenesis, 58 morphology, nonmammalian, 8-10, 9, 13 neurons, quantity in, 12 nonmammalian vertebrate, 9 norepinephrine release in, 327-328 systems analysis applied to, 380-382, 381 tissue culture, 91-95, 96 vertebrate and invertebrate compared, 798-801, 799, 800 central nervous system development, 62 cell migration, 100ff, 101, 102, 103-104 cell proliferation, 100, 101, 102-103 dynamics, 53, 54, 56 macrodeterminacy, 54 microdeterminacy, 54 selectivity, 58, 59 zones, 100 cephalopods dendritic field, 810 cerebellar cortex cell aggregation in vitro, 106 functional organization, 413-419 glomerulus in, 430 granular layer, cell development in, 103, 103 internuncial neurons, 419 morphological organization, 409-413 Purkinje cells, 103, 103 stimulation in alligator, 421 cerebellar glomeruli, 427, 429, 431, 435, 440, 441 as an excitatory synapse, 429 as an inhibitory synapse, 429 axon terminals, 427 dendritic terminals, 427 ultrastructure, 429 cerebellum, 409-426, 466, 468, 469 as a closed-loop system, 424 as an open-loop system, 424 basic circuit, 409-411, 413 function, 379, 423-424 and motor skills, 415 neuronal fabric of, 55 neuronal operations in, 409-426 neurons in, 55 relationships of neural elements, 416 cerebellum, fetal cell proliferation and migration, 101 neuron differentiation sequence, 139 cerebral cortex, 445, 449, 450 brain waves, 244-246ff evoked potential, 244-246ff, 250-254, 255 evolution of, 7-26 function in visual pathway, 377 homology, 22, 361 mammalian and nonmammalian, 10, 11, 22ff, 24 neuron differentiation sequence, 139

neurogenesis, 65, 139 ontogenetic derivation of neurons, 24 photically responsive areas, 342, 343 phylogeny, 19ff, 339 sensory representation, properties of, 613 see also allocortex; corpus striatum isocortex; external striatum; visual cortex cerebral dominance aphasia and, 362 handedness and, 362, 362 language disorders and, 365 cerebral hemisphere, nonmammalian, 9 morphology, 8-10 sensory conduction to, 9, 16 cerebral lesions, see brain lesions cerebral tissue conductive changes and information storage, 225 electrical impedence, regional modifications, 240 nerve membrane polyanions, 239-240 cerebrospinal fluid ionic environment, 787 turgor, 58 cerebrum neurogenesis, 64 tissue culture, 92, 94-95, 96, 98 chain elongation factors in protein synthesis, 923, 924 chelation free energy, alkali ion and, 687, 687 chemoreception, 511, 516, 517 silk moth (Bombyx mori), 514, 515 see also insect olfaction chemotaxis in nervous system, 123, 126 chick embryo brachial nerve plexus, 112 deafferentation, 143-144, 143, 144, 147 dissociated sensory ganglia of, 84-99, 87, 88, 90-93 electrical activity, 144-147, 146, 148 hatching, preparation for, 149 innervation of limbs, 112 integrated movement, 149 motility, 142-144, 142, 144 stimulated movements, 149-150 chicken hatching behavior, 149 pecking behavior genetically determined, 193 child development, 176ff, 179ff verbal stimuli role, 183 see also cognitive development chimpanzee EEG patterns of decision-making, 233, 234-236, 236 object use by, 43, 44 social behavior, 43, 44 speech, lack of, 54 see also apes (Pongidae) cholesterol hydrocarbon chain motions inhibited by, 703 choline acetyltransferase localization, 765 cholinergic terminals organization of, 764 chordamesoderm, 62 chromaffin cells of mammalian adrenal medulla, 532. 533 PNMT in, 532, 533 chromatolysis, 73

effects in peripheral nervous system, 81 ventral-horn cells, 78 see also cell death chromogranin release from adrenal medulla, 775, 775 release from synaptic vesicles, 326 see also protein synthesis chromomeres, 983-985 chromophores of fly's compound eye, 497, 498, 509 chromosomal rearrangements in Drosophila, 980 chromosomes, 975 chromeric organization, 983, 984, 984 protein role in organization of, 1010 chromosomes, lampbrush, 968, 974ff, 975-978 980 morphology and function, 974, 975, 975, 977 chromosomes, polytene, 985, 988 ciliogenesis ventricular cells, 64 cilium ventricular cells, 64 circadian rhythm, 264 circuits characteristics, 384-385 chemical, 386 defined, 487ff extrinsic, 134-135 hypothalamic, 208-211 intrinsic, closure of, 132-134 lateral inhibition, 389, 394 models of, 385-388, 392-393 orientation, effects, 384, 386 questions on, 386-389, 386-388 structural context, effects, 384, 386 subsystems and, 386-387 see also neural circuits circuit theory, 384-389 characteristics of circuits, 384-385 circuit element, abstract, 384 first-order processes, 388 input-output signal interpretation, 387, 388 mechanistic analysis of circuits, 386-387 neural circuits and, 389, 391, 393 synthesis of circuits, 386-387, 387, 389 see also electrical resistor; neural circuits clearing system, 415 climbing fibers, 409ff functional properties, 413, 414 Purkinje cell system and, 413, 413 clonal commitment, 893 CNS, see central nervous system (CNS) code defined, 574 experimental, 574-575 natural, 574-577 see also neural codes coding, see neural coding codon system, 419 Coghill, G.E. embryonic behavior theory, 130, 133, 139, 141, 148ff cognition language and, 183, 367-368, 370 Piaget and, 179 sensorimotor, 179-181 signal systems, 183 Soviet concepts, 183-185 see also perception cognitive development, 177 cross-cultural studies, 180

educational methods and, 185-186, 292-293 environmental feedback, 184 learning disorders and, 292 maturation and, 180 organismic concept, 176-177 perceptual processes, 184 Piaget's stages, 179-181 Soviet theories, 183-184 training and, 180 verbal stimuli and, 183 cognitive development theory, 176-177, 181 behavioristic, 177, 181 organismic, 176-177, 179 Piaget, 177, 179, 180, 181, 186 Vygotsky, 183-184 Zaporozhets, 184 cognitive disorders etiologies, 367 Funktionswandel, 367 jamais vu phenomenon, 366 language disorder similarities, 366-367, 371 presque vu phenomenon, 366 simultagnosia, 366 symptoms, 366-367 see also language disorders cohesive ends of bacteriophage lambda DNA, 956, 957 coincidence detection, 418 coincident-current selection techniques, 454 colchicine axoplasmic transport inhibited by, 851, 852, 855-856 effect on axonal flow of acetylcholinesterase, 846, 848 coliphage, see bacteriophage lambda collaterals, recurrent in cortex, 450, 450 neuropil and, 451 of pyramidal cell neurons, 448, 455 in ventrobasal field, 452 colliculectomy effect on visual perception, 323 color contrast, 304 Land effect, 304 command fibers, 402-404, 408, 490ff in crayfish oscillatory drive system, 402 in crayfish postural control, 402, 403, 403 see also interneurons command neurons, 489, 490-491, 865 communication, 302 and coding in CNS, 569-671 interneuronal, 572 neuroendocrine, 519-529 see also social communication communication theory, see information theory comparative neurology, 27, 37 homology of neuronal systems, 8 comparative psychology, 34ff experimental difficulties, 36-37 learning sets, 34 motivational conditions, 36 see also ethology compartmental models of neurons, 553, 555 compound eye, see eye, compound computers neurophysiological analogies, 486-487ff computer applications EEG patterns, recognition and analysis, 234ff, 236 concept formation, 177 language and, 182-183

see also cognitive development conceptualization, 369 see also predication conditioned avoidance response adaptive behavior, role in, 330 affective state effects, 330 catecholamine depletion, effects on, 328 conditioning genetic influences, 189 protein changes and, 278-289, 283-287 conditioning, classical, 170, 171, 218 cellular mechanisms, 260 limbic system function and, 346 neuron self-re-excitation and, 262, 267ff synaptic interaction and, 261, 262 conditioning, operant, 171 biochemical changes in hippocampus during, 282-283, 284, 285, 288 brain wave modification by, 250, 250, 251, 251, 254 of CNS electrical activity, 222 of evoked potential, 249-254, 250-253, 255 of glandular responses, 222 of heart rate, 218-220, 219, 220, 221 homeostatic imbalance and, 222 of intestinal contraction, 220, 221 reinforcement of visceral response, 218, 219-220 of urine formation rate, 222 conditioning, sensory biochemical changes in hippocampus during, 287, 287, 288 protein changes during, 286-287, 287, 288 conduction mechanism, see nerve activity conduction pathways, see nerve pathways conformation in lysozyme-inhibitor complexes, 904, 904 noncovalent forces affecting, 901 congruent points, see corresponding retinal points contrast transmission in fly's compound eye, 504, 505, 509 corpus gangliothalamicus, 102, 102 corpus striatum, 464, 465, 466, 468, 469 homology, 19-20, 22-25 nonmanimalian morphology, 10 see also external striatum corresponding retinal areas extraocular muscle synergy and, 472 corresponding retinal points, 477, 478, 478 binocular parallax and, 477 binocular single vision and, 482 fiber connections in striate cortex, 478 receptive field disparity, 477, 478, 478 cortex binocular depth discrimination in, 471-485 cell matrix, 449 defined, 8fn form vision in, 471-485 limbic system and, 346 olfactory bulb and, 539-552 synaptic organization in, 642, 643 see also allocortex; isocortex; cerebellar cortex; cerebral cortex; striate cortex; visual cortex cortical field potentials experimental, 555, 557, 557 cortical map nonorientable surface property of, 611-612, 612 somatosensory area I, peripheral stimulus configuration, 613, 614 spatial characteristics, 611-612 tactile-kinesthetic representation and haptic

sense, 613 cortical mapping, 605, 615 homeomorphism, 608-609ff, 609 lifting function, 614, 614 path-lifting property, 613ff, 614 somatosensory spaces and, 613-615, 614 cortical plate cell migration to, 101, 104 cortical pyramid, 448-449, 448 modularization, 448, 448 cortical readout system, 454 cortical system defined, 539 corticosteroids long-term memory and, 273 corticosterone, 532 corticothalamic reflex, 453, 454, 456 cortisol, 531 crab (Limulus), see eye, compound cranial nerves conduction pathways, 14 crayfish command fibers in, 402, 403, 403 giant fibers, 399, 401, 402 interneuron, dendritic branching in, 802, 806 interneurons, 399, 402, 402, 403 motor neurons, 399, 401, 402, 403 nerve-cord, 851, 853, 855 neuropil, 399 swimmeret, beat in, 402 synaptic membranes of nerve cord, 716, 717 crustaceans gaglionic neurons, 54 see also crab; crayfish; lobster culture media, 83-84 collagen, 86, 89, 95 dissociation of neurons and, 86 maturation and, 84-85 nerve growth factor (NGF), 84, 86, 87, 89 plasma clot, 85-86 cutaneous nerves receptive fields, 118, 119, 122, 153 reflexes, on skin graft, 118, 120 specification, peripheral, 117-118, 119 see also skin grafts cycloheximide memory, effect on, 274, 274 protein synthesis inhibition by, 273, 273 cytomembrane, see cell membrane cytoplasmic basiphilia, 806, 809 cytotypic maturation, 84, 89

D

Dale's law, 779 data transmission, see neural transmission deafferentation, 143 spinal cord, chick embryo, 143-144, 143, 144 trigeminal ganglion, 143 decision-making, 492ff EEG paterns, 230, 233, 234-236, 236 psychological set for, 228 decoding defined, 576 degradation of messenger RNA, 921, 922 Deiters' nucleus antigens, 279-281, 280, 281 immunological study of, 279-281, 280-281 déjà vu phenomenon, 342

dendrite branching patterns, 801-802, 806 defined, 547 differentiation of, 134 electrical properties, 860-861 formation, 69, 70 full action potential not required for function, 548 in LGB glomeruli, 431, 432 retinal ganglia, density in, 632, 633, 634 terminals, 427, 429, 440 types of, 548 dendritic branch electrotonic length, 553 dendritic branching mathematical model, 552, 553 dendritic neuron theory, 552-565 dendrodendritic inhibition, 548 dendrodendritic synapses, 552-565, 561, 562 two-way postulate, 560, 562 depression drug metabolism and, 328 electroconvulsive shock and, 328 norepinephrine deficiency in brain and, 328 depth perception, 471, 484-485 animal, neural mechanisms in, 472, 484 binocular mechanisms, 478-482 Julesz's studies of, 471-472 neural mechanisms for, 472 parallax as basis for, 477 pattern analysis and, 311 random-dot patterns, 471-472, 471 receptive field disparity role, 478 dermatome representation in somatosensory area I, 606, 608 development, hormonal, 197 development, neural, 53-61 dichroic absorption properties of fly's compound eye, 497, 498, 509 diencephalon cell proliferation, 65ff neuronal origin, 65ff, 70 see also epithalamus; thalamus dinitrophenol, 681 diplopia, 479, 482-483 disfacilitation in Purkinje cells, 423 disparate retinal points, 485 see also corresponding retinal points; receptive field disparity (vision) displacement behavior, 209 electrically stimulated behavior similar to, 209-210, 209, 211 dissociation factor in protein synthesis, 923, 924, 924 division of labor, 44 DNA of bacteriophage, 994 of bacteriophage lambda, 955-957, 956, 957 content per cell, 985-988, 987, 988 content per gene, 980, 981, 981 content per nucleus, 988 denaturation and annealing of, 992, 992, 993, 994, *994* of E. coli, 956-958 evolution of, 920 gene expression control, 884 histones and, 981 lambda, 958ff, 959, 960 prophage, 957

protein recognition system, 955-962 profile of, 999ff, 1000-1003, 1008-1010 protein repressor interaction, 884 pulse-labeled, 1002 recognition sequences in E. coli and bacteriophage lambda, 958-960 repeated sequences, 963-965, 991-994 repetitious, evolution of, 965ff sequences, coevolution of, 965, 966, 968, 969, 970 subunits of, 999-1003 translocation, 884 transposition, 884 virus and, 930, 931 see also gene, master; gene, slave; protein DNA, chromosomal, 999-1010 adenine-thymine segments, 999, 1002, 1005, 1006, 1008, 1010, 1011 2-micron subunits, 1001, 1003, 1004, 1006-1010 primer-initiator subunit, 1003 replication, 1001, 1002, 1003, 1004, 1005-1006, 1005, 1007, 1008, 1008, 1009, 1010 satellite, 999, 1007, 1007, 1008, 1009 7S subunit 1002, 1005, 1006 80S subunits, 999, 1000, 1001, 1003 DNA, duplex, 991 DNA, mitochondrial, 827-828 gene products, 829 DNA, neuronal synthesis, 67, 122-123, 156 DNA, repetitious, 964, 965 evolution of, 965, 966 DNA ends of bacteriophage lambda, 955, 956, 956, 957, 957 of prophage, 957, 958 DNA replication, 841, 994, 994, 999 DNA-protein recognition, 955 domain hypothesis, 894, 896, 896 dopamine, 769, 770, 770 appetitive behavior, effect on, 329 release, 326 reproduction of rats, role in, 526 in telencephalon, 327 see also epinephrine; norepinephrine dorsal spinocerebellar tract (DSCT) information transfer efficiency, 624-625 input-output relationship, 618, 619 linearity of input-output relationship, 618ff, 619 neuronal firing pattern in, 619-620, 620, 622ff neuronal firing threshold in, 622 neuronal excitation, 618, 619 second-order neurons in, 617, 619 simulation of output rates, 577 synaptic coupling specificity, 617-618 double vision, 479, 482-483 drinking stimulus-bound, 210ff drive state function, 216 self-stimulation and, 210-211 stimulus-bound behavior and, 210-211, 214 reinforcing stimulus and, 216, 216 Drosophila chromosomal rearrangements in, 980ff, 980 paramutation in, 968 duck imprinting and adult sexual choices, 191 DSCT, see dorsal spinocerebellar tract

Ε

E. coli DNA of, 956, 957 elongation factors in, 923 lactose metabolism in, 947ff, 947 recognition sequences in DNA of, 958-960 ribosomal structure, 913ff, 913 ribosomal subunits in, 926 EAG see electroantennogram eating stimulus-bound, 210ff ectoderm, 62 see also neural plate; neural tube educational methods cognitive development and, 185-186 learning theories and, 185-186, 292-293 EEG analysis of alerted cat, 230, 231, 232 autospectral, 229 by computer, 234ff, 236 cross-spectral analysis coherence, 288, 230ff, 232 of monkey, 232-233, 233 mathematical techniques, 228-229 phase relations, 226-228 prediction of motor responses from, 233-236, 294 of short epochs, 229ff step-wise discriminant analysis, 237-238, 238 EEG patterns, 224-243 amplitude distribution, 225-226, 227, 228 in cerebral systems, interrelationships, 228-232 232 of decision making, 233-236, 236, 238, 294 during psychological stress, 233-239, 237 stepwise, 238, 239 during visual discrimination, 232-233, 233 see also brain waves electrical brain rhythms, see brain rhythms, electrical electrical brain stimulation, 172, 173 behavioral responses, 355 EEG and, 225-226 genital responses, 351, 355 hypothalamus, 208, 211, 212, 215 of limbic system, 351, 377 motivational reactions, 208 "reinforcing brain systems", 208, 214-215, 215 social signal analysis by telestimulation, 355 telestimulation, 355 vocalizations elicited by 353ff, 354, 359 see also stimulus-bound behavior electrical resistor behavior, 384 system representations of, 385 see also circuit theory electrical systems, see circuit theory electroantennogram (EAG), 512, 516 electroconvulsive shock retrograde amnesic effects, 273-274 electron microscope cell culture preparation for, 95 neural circuit mapping applications, 389, 390, 391 scanning, 389-393, 390, 391 electron transport in mitochondria, 831-832 electronic data processing, see computer applications elicited behavior, see stimulus-bound behavior

embryo archenteron, 62 motility, 141-151 nervous system, topographic mapping in, 108 neural tube origin, 62 see also chick embryo; monkey embryo; motility, embryonic; nerve-fiber connections; nerve-fiber growth; etc. embryogenesis, 290 emotion, 302 affect and, defined, 337 biogenic amines and, 324-336 brain correlates, 338ff, 347 brain waves and, 236 defined 337 electrical brain stimulation and, 208 limbic system functions in, 339ff triune brain and, 336-349 see also affect emotional cerebration, 337 see also affect endocrine action on neurons, 78 endocrine cells, 519ff communication properties of, 530, 531 control of by innervation, 520, 522 control of by neurosecretory neurons, 521 information transfer, 531 neural control by innervation, 520-521, 526 endocrine transducers, 527 see also neuroendocrine transducer cells endoplasmic reticulum, 678 axon regeneration and, 806, 808, 810 neuronal protein synthesis and, 808 endplate potential histograms, 775 see also motor endplate potential ensheathment, see glial ensheathment, myelin sheath entopeduncular nucleus, 465, 467 environment behavioral development affected by, 190-193 enzyme mutation effects, 815 see also species of enzymes ependyma cell differentiation. 64 ependymal zone, 63 epidermal growth factor (EGF), 822 epidermis, 62 epigenesis, 292-293 epilepsy affects during seizure, 341-342 aura, 342 déjà vu phenomenon, 342 hippocampus and, 341 isocortex functioning during seizure, 342 limbic cortex and, 341, 342 memory and, 342 perception during seizure, 342 psychomotor, 341 epinephrine, 324, 531, 532, 532, 533, 533 emotion, role in, 324-325, 327 see also norepinephrine epithalamus neurogenesis, 65, 67, 70 proliferative gradients, 67 epithelium epithelio-mesenchymal interactions, 80 mitosis in, 63 synaptic junctions, "tight," 722

see also spongioblasts episynaptic interaction synaptic consolidation, role in, 263, 263 EPSP (excitatory postsynaptic potential), 452-453, 459ff "all-or-none", 459-460, 460 alternation with IPSPs, 450, 461-462, 461, 462, 467, 468 amplitude and neuron-firing characteristics of, 623ff characteristics of, 459 correlated spike discharges and, 580 cortical cell response, 645, 646 duration and cell threshold, 639, 640 elicited by septal stimulation, 346, 347 heterosynaptic facilitation, 263 from lateral geniculate relay cells, 638-639, 639 membrane potential, effect on, 583, 584 in monkey, 346, 347 muscle stretch effect on, 621, 621 motor neuron spike trains and, 446 regular and irregular, 584 short-latency, 462 summation, noncommutative, 578 unitary, of second-order neuron, 621 in thalamus, 463-467 in visual cortex, 642 see also IPSP (inhibitory postsynaptic potential); PSP equilibrium dialysis, 948 ergodic processes, 601, 603 erythrocyte amphiphilic spin label orientation, 698 escape response, see avoidance behavior estrogen, 532 lordosis reflex and, 199 ethology, 188, 194 adaptation and, 41-42 hierarchical structure of behavior, 177, 178 see also adaptive behavior; animal behavior; comparative psychology eukaryotes, chromatid, 973 chromosomes of, 884, 962, 974, 998-1013 differences between prokaryotes and, 873, 962, 963 differentiation in, 898 differentiation systems in, 885 DNA in, 884, 964, 965-970 genes, arrangement and evolution of, 884, 962-972 mechanisms in, 873 molecular genetics in, 884 multiple genes in, 885 mutation rate in, 977, 977 protein systems, 883-884 recessive point mutants in, 994-995 recombination in, 980 eukaryotic chromosomes structure and replication, 998-1013 evoked response bioelectrical origins of, 243-248 evoked potential, 243-259 averaged, for cats, 251 behavior and, 248-249 coding and, 243-249 criterion response, in cats, 255 flash-, 253, 256 independence of cortex and geniculate, 255, 256 late-wave conditioning in humans, 250

mean amplitudes, 252 neural coding and, 254 operant conditioning of, 249-254, 250-253, 255 origins, bioelectrical, 243-248 sensitivity to optical patterns, 312 evolution, 54 adaptive trends, 40-41 of brain and behavior, 5-47 study of, 5-7 theory, 39-40 see also phylogeny evolution, extracellular of replicating molecules, 927-945 evolution, precellular of DNA, 930 of RNA virus, 930 evolution, primate fossil record, 40 human, 42 living forms, 40 theory, 39 evolution theory, 7-8, 39-40, 45-46 time scale influence on, 40 synthetic theory, 39 evolving movement theory, 424 excision, 953, 959, 960 of bacteriophage lambda DNA, 957, 957 excitatory junction, 574-575 excitatory postsynaptic potential, see EPSP (excitatory postsynaptic potential) exocytosis, 726, 776, 872-873 in adrenal medulla, 775-776 synaptic vesicles and, 725 experimental code defined, 574-575 experimental procedure, see methodology explant culture, 83-84, 91, 97, 104 bioelectric development, 85, 92ff CNS tissue, 91-94 nerve fiber outgrowth, 85 synaptic function and connections, 92, 94, 97 see also cell culture; culture media external striatum, 16 embryonic development, 23, 24 homology, 18, 22, 24 neuroblast migration, 23, 24 exteroceptive feedback, 408 in grasshopper flight control, 405, 406 extracellular space between neurons and neuroglia, 784, 787, 792 eye connection with brain, 118-119 nerve fiber connections of rotated eye, 120-122 eye, compound, 497, 498, 509 of fly, 494-509, 497 inhibition effects on signal transmission in, 627 lateral inhibition in, 389 light flux modulation, 499 light-shadow transitions on model of, 392 movement perception in, 501 of Musca, 497 neuron firing characteristics, 624, 666 optical representation in, 500, 501 sensitivity distribution in, 503 visual transduction in, 391ff, 393 see also ommatidia; optical ganglion lamina; optic cartridges; rhabdomeres eve dominance receptive fields of striate neurons and, 476-477

F

fact defined, 337 fasciculation, 85, 89, 111-112 see also explant culture; nerve fibers; organotypic maturation fatty acid, see lipid "feature detectors," 305, 308, 311-312 Fechner's law, 303, 304, 306 see also Weber's law feedback exteroceptive, 408 in grasshopper flight control, 405, 406 loops, 385, 386 positive feedback network, 398 system, 419 fetal brain cell migration in, 101, 102, 102 corpus gangliothalamicus, 102, 102 fibers, see muscle fibers; nerve fibers fibrocytes, 84 in vitro development, 85 see also spindle cells firing, 270, 648 control calculations, 653ff, 654, 655, 656, 657 control of, 295 ergodicity, 601, 603 probability, 653 frequency coding, 598, 601, 602, 603-604 by internal stimuli, 346 latency of response, 244, 245 PST histograms, 649, 651 rate, input intensity and, 618ff, 619 single-cell probability of, 244, 246-247, 246, 247, 248 see also spike firing pattern brain waves and, 226-228, 228, 229 detection of change in, 648 DSCT neurons, 619-620, 620, 622ff EPSP amplitude and, 623ff information transfer efficiency and, 627-628 inhibitory input effects, 625-627, 626, 627 models, 622ff of muscle spindles, 623, 623 physiological significance, 624-625 serial dependencies in, 620, 622 see also spike trains fish nerve regeneration, 154-155 Mauthner neurons, 398, 398 phylogeny, 27-28, 28 reciprocal inhibition network, 398, 398 fluorodeoxyuridine, 1005, 1006, 1008, 1009 fly compound eye, 494-509 flight motor neuron, 400 pattern generators, 399 rhabdomeres in eye of, 495ff forebrain, avian, 15, 19ff, 20 auditory system, 22 visual system, 20-22, 22 see also avian brain forebrain, mammalian, 19 function, 10 homology, 18-20, 22 phylogeny, 10, 12 forgetting, 165-167 see also memory form perception, 310ff

colliculectomy effects, 323 contour analysis, 476 de-striation effects, 323 distortion, 313, 313 Frazier "spiral," 310, 311, 313 inhibitory effects of inappropriate stimuli, 476 pattern recognition and, 472 split-brain effects on, 322 frequency sensitive gate nucleus reticularis thalami as a, 452 fossils, 40, 45 living forms and, 40 Fourier transform spike train analysis by, 595-596 fractionation techniques subcellular, 761-768 Frazier "spiral," 310, 311, 313 frog cell differentiation, ablation effects, 79 climbing fibers, 410 mating calls, 394 photic regulation of melatonin synthesis, 534 pineal cells in, 534 reflex, misdirected, 117-118, 120, 121 retina, 394 rotated skin grafts, 117-118, 120, 121, 153 "sameness" neurons in optic tectum, 378-379 wiping reflex, 153 see also skin grafts functional adaptation of neurons, 843 functional analysis of 16S ribosomal RNA, 917, 918 of 30S ribosomal proteins, 916, 917, 917 Funktionswandel, 367 see also cognitive disorders

G

GABA (gamma-amino butyric acid), 770, 770 binding sites in nerve, 793, 794 biosynthetic pathway, 772 gamma globulin, see immunoglobulin ganglia dissociated sensory, 87, 88, 90-93 mollusk and crustacean, 54 nerve growth factor inhibition, effects of, 816-817 ganglia, arthropod, 397–409 genetically programed structures and functions, 489 hierarchical organization, 403, 408 neuronal impulse-burst capabilities, 398, 403 pattern generators, 397, 398, 399, 402, 404 sensory filters, 397, 404 ganglia, cardiac, 387-388, 389 decomposition, 388-389 input sources, 395 orientation in lobster, 394 ganglia, retinal, 631 biochemical specificity, 120 cell adhesiveness in, 123 dendritic density of, 632, 633 differentiation, 122 neurogenesis, 120-122 nonlinear signal summation in, 636 optic tectum connections, 120-122, 123, 124 receptive field center, 631, 632, 636 receptors, excitation of, 631 sensitivity, dendrite density and, 632, 634 sensitivity to stimuli, 632

specification, 120ff, 756, 757 specification of connections, 122 stimulus intensity-response curves, 632, 635-638 ganglia, spinal, 62 cell cultures, 84-85, 87-88, 90-93 ganglia, sympathetic, 62 gene activity, 823 amplification, 963, 966, 968 conversion, 897, 897 conversion, "democratic," 969, 970 DNA content, 980-981, 981 duplication, 893, 894, 896, 927-928 expression in brain cells, 873-874 eukaryotic, arrangement and evolution of, 962-972 mispaired, 968ff multiple, 884, 897 number per genome, 989 recombination, see gene, master; gene, slave regulatory, 946ff reiteration, 966, 967 series, see gene family structural, 946ff translocation, 893, 893, 925, 960, 963, 966, 970 gene, master, 968-969, 969, 974 mutation, 977ff, 977, 979 recombination, 977ff, 979, 980, 981, 982 structure of, 968 theory of, 973-998 genes multiple coevolution, 966ff gene, Mendelian chromomeres and, 983-985 gene products int, 958, 959 xis, 958, 959 gene, slave, 969, 974 recombination and, 982, 983ff reconstitution, 980 structure of, 968 gene expression in brain cells, 676-677, 873-874 in nervous system, 812-827 gene family, 973ff in Drosophila, 981 duplications and, 982 linear DNA and, 973 in prokaryotes, 974, 974, 980 recombination of, 979-980 size alterations in, 985, 986-987 gene product int, 957, 958, 959 xis, 957, 958, 959 generative grammar, 178, 368-369, 369 genetic control and repressors, 946-954 genetic determinants of behavior, 189-190, 192 genetic determination neuronal connections and, 126-127 genetic disorders of sexual development, 196, 197ff, 200 phenylketonuria (PKU), 189-190 genetic inducer, 948-952 genetic induction in vitro, 950 nature of, 951, 952, 952 genetic operator, 946-948, 952-953 repressor affinity for, 950-951 genetic preadaptation, 73, 76

genetic promoter, 948, 950 genetic recombination, 960 genetic repressor, 947, 948, 952 affinity for operator, 950, 951 bacteriophage lambda, 950, 952, 953 binding to operator DNA, 949 lactose as, 950, 950, 952, 953 nature of, 948, 949 genetics of antibodies, 885-900 behavior, 189-190 and neurosciences, 925 geniculate body, see lateral geniculate body; medial geniculate body genital display cerebral representation, 352 innate and learned components, 352 in squirrel monkey, 351, 351, 352 as social signal, 351, 351, 352 vocalization and, 354-355 Gestalt theory of behavioral development, 290 giant fibers of crayfish, 399, 401, 402, 403, 404 gibbon, 43 glandular secretion neurosecretion and, 779 neurotransmission and, 774 glandular responses, see learned glandular responses glia, see neuroglia glial capsule, 427, 435, 446 glial ensheathment, 782ff "loose," 784-787, 791-794 specializations of, 787 types of, 783 see also myelin sheath; neuroglia; Schwann cells glioblasts, 69 goal-directed behavior forebrain role in, 10 globus pallidus, 465 glomeruli geniculate, 434 in LGB, 432 of olfactory bulb, 541, 546, 547, 549 pulvinar, 436 synapses in, 431-433 thalamic, 435-438 glucocorticoids, 533 glutamate as neurotransmitter, 770, 771 glycolipid carbohydrate residue on neuronal surface, 748 cellular localization, 750 in nervous system, 747 glycomacromolecules brain, 747-760 on cell surfaces, 750, 751, 752 cellular localization, 750 interneuronal recognition and, 747-760 at synapses, 751, 752 see also glycoproteins glycoproteins acetoxycycloheximide and, 751, 753, 753 in brain, 750-751, 754, 755, 756 carbohydrates and, 748, 749 cellular localization, 750 degradation, 749-750 developmental studies, 753 interneuronal recognition, role in, 750

metabolism, 748-750, 751, 753, 754 polysaccharide chains, 748 precursors, 754, 754 structure, 748, 749 transport, 753, 754 turnover at nerve endings, 753, 753 glycoprotein synthesis, 748, 751 synapse formation, role in, 754 acetoxycycloheximide and, 753 brain maturation and, 751, 753ff, 755, 756 glycosyl transferases, 748 in brain, 751 polysaccharides and, 757 Golgi cells, 411, 419, 427ff axon inhibition of granule cell dendrites, 429 axon terminals, 427, 429, 429, 440 dendritic terminals, 427, 429, 440 as feedback system, 419 as gating device, 419 Golgi type II cells description of, 431, 433, 435 inhibitory effects of, 433 as local circuit, 445 as part of module, 449 gonadotropins, 530 gradients of inducers retinal and tectal cell specification by, 756ff, 757, 758 grafts, see skin grafts grammar, transformational, 178, 368-369, 369 granule cells, 65, 69, 70, 411, 413, 414, 416, 418, 419, 559, 560, 562, 563 activity, 560 dendrites, 541, 544, 546-549 dendritic excitation by mossy rosettes, 429 dendritic inhibition by Golgi cell axons, 429 dendritic terminals, 427, 429, 440 developmental sequence, 103, 103 functional properties, 415 of olfactory bulbs, 541, 542, 544, 546, 547, 549, 550 grasshopper courtship behavior, 407-408 flight control, 397, 398, 398, 399, 404-406, 490 leg control, 407 pattern generators, 399-408 proprioceptive feedback, 405, 407 stretch receptor, 404-406, 405, 489 visual control of roll reflex, 405, 406 growth cones, 131, 132, 133, 134 GTP (guanosine triphosphate) as energy source, 828

Н

habenula neurogenesis, 67, 70 neuron types in, 67 see also epithalamus; ventricular zone hamster cell growth in vitro, 74 destriate, 323 hand skills cerebellum evolution and, 45 handedness aphasia and, 362 cerebral dominance and, 362, 362 reversal in rats, 281-285, 282, 284 haptics defined, 613 hatching behavior

in chickens, 149 heart rate training, operant, 218-220, 219, 220, 221 behavioral consequences, 221-222 Hering's law, 472 hermaphroditism, 205 heterosaccharides, 756 surface, of retinal and tectal cells, 756 heterosynaptic facilitation (HSF), 263-264 episynaptic action and, 263 as a memory mechanism, 263-264 minimal latency, 264 optimal interstimulus interval, 264 specificity, 263-264 HIAA, see hydroxyindole acetic acid hind-limb cortical representation, 606, 608, 608, 609, 610, 611 HIOMT, see hydroxyindole-O-methyl transferase hippocampal formation cell alignment, 105 cell pattern, reaggregated, 105-106, 105 cell proliferation, 68 differential action on neuron inputs, 345ff, 346 intracellular recordings, 347 neurogenesis, 64, 65 olfactory stimuli elicitation of EPSPs, 346, 347 pyramidal cell firing, 226-227 see also area dentata; hippocampus; retrohippocampal formation; septum; subiculum hippocampal gyrus, 345 functions, 342-343 photic stimulation of, 342, 343, 344 hippocampus amnesia from electrical stimulation, 172 amnesia from lesions, 172, 173 EEG data from, 231 epileptogenic focus, 341 location of, 68 memory, role in, 231-232 memory stimulation in, 173 neural circuit interactions, role in, 229ff, 233, 346. 347 neuronal origins in, 68 neurons and learning, 282ff, 284, 287 protein in, neuronal, 282, 284, 285, 288 see also hippocampal gyrus histiotypic aggregation, 86, 88, 89 histograms, cross-interval, 651ff, 654-658 peristimulus-time, 649ff, 651, 659 histones, 981, 982, 983, 985, 1010 homeostasis visceral conditioning and, 222 Homo erectus, 44 homologous response, 110, 153-155 to homonymous muscles, 109-110 homology antibody regions, 894, 894, 895 brain, 11 cerebral cortex, 361 corpus striatum, 19-20, 22-25 forebrain, 10, 18-20, 22 lemniscus, 14 mesencephalon, 16-17 neocortex, 18 neuronal systems, 8 regions, 896, 896 responses, 153-155 rhombencephalon, 10 thalamus, 14

vocal system, 357 homosexuality hormonal influences on, 200 hormones adrenocorticotrophic (ACTH), 333 behavioral maturation, role in, 293-294 cortical synapses and, 333 deficiencies, 197-199 gene activity and, 823 influences on sexual behavior, 196-207 sexual development affected by, 196-207 and social behavior, 201-205, 202-204 steroid, 333 testicular, 199-205, 204 see also names of specific hormones; neurohormones; testosterone horopter, 477ff, 478 hydrogen bonds in lysozyme-inhibitor complexes, 904 in proteins, 902, 903, 903 in ribonuclease-nucleotide interactions, 907, 908 hydrocarbon chains, 701-703 double bonds, 702-703, 702 low-energy conformation, 702, 702 melting, 701-702 molecular fluidity and, 703 motion increased by cholesterol, 703 unsaturation and perpendicular transport, 704-705 hydroxyindole acetic acid (HIAA), 535 hydroxyindole-O-methyl transferase (HIOMT), 534, 535 hyperplasia, 78, 79, 80 hypophysiotropic hormones, 531, 532 hypophyseal portal system, 525, 526 hypoplasia, 78 hypothalamus electrolytic lesions between brainstem and, 211-212 neural circuitry for drives, 291 neurohormones released by, 521, 527, 530ff neurosecretory system, 778-779, 778 stimulation effects, 208, 209, 211, 212, 215, 216 hysteresis in insect muscle control, 406-407, 407

I

identical retinal points, see corresponding retinal points immune response, 885ff adaptive, 885 diversification in, 893 translocation hypothesis, 893 immunity mechanisms, 884 immunoglobulin, 885ff, 995-996 7S antibody increase in, 885 antigen-binding function, 894, 895 effector functions, 895 gamma G, 885ff, *886*, *895* gamma M, 885, 885 synthesis of, 885ff see also amino acids; antibodies imprinting, 190-191 individuality, sense of, 342 aura and, 342 limbic system and, 346 neural mechanisms, 342ff

self-orienting nature of affect and, 346 information from spike trains, 587 information processing, 486-487, 489 hierarchical, 492ff information registration defined, 164 information retention defined, 164 information retrieval, 173 defined, 164 in primary memory, 166, 168 in retrograde amnesia, 164 in secondary memory, 167-168 in tertiary memory, 167-168 puromycin effects in, 275 information storage, 163 and amnesia, 164 in CNS, 397 in primary memory, 166 in secondary memory, 166, 168 in sensory memory, 165 in teritary memory, 167 nerve membrane structure and, 240 neuronal sites of, 260-261 nonsynaptic, 264-270 by synapses, 261-264, 262, 263 information theory, 355-356, 572 dominance behavior and, 356-357, 356 neural transmission and, 624 neurophysiological application, 572-574, 573, 574 social communication and, 355-357 stochastic analysis of bidirectional communication, 355-356, 355, 356 information transfer, 173 brain electrical rhythms and, 224 in cerebral systems, 232 efficiency, firing pattern and, 627-628 interneuronal, 665-666, 667 retrograde, 79, 80 information transmission (in nervous system), see neural transmission information updating in ventrobasal cell matrix, 446 inhibition, 492 excitation and, 491-492 reciprocal, 393 recurrent, 490 functional, 491 lateral, of mitral cells, 562 self-, of mitral cells, 562 see also IPSP; lateral inhibition inhibitory postsynaptic potential, see IPSP initiation factors in protein synthesis, 923, 924, 924 innervation limbs, 112 muscle cells, 111 rotated skin graft, 117-118, 119, 121 and spinal cord of chick embryo, 80 see also nerve-fiber connections insect olfaction, 511-518 Poisson distribution and, 515-517, 515 receptors, 511, 512-513, 513 signal-noise ratio, 515 transduction, 516-517 receptor cell response threshold, 512, 514-516, 515 insects acetylcholine effects in nervous system, 792

antennae, 512, 516 eye of, 494-511 ganghonic neurons, 798, 799, 800 motor-control systems, 490 muscle, 407 olfactory receptor cells, 513ff, 513 sensillum, 513, 513 sensillum liquor, 513, 514 sexual attractant, 512-513, 517 see also pheromones; silk moth (Bombyx mori) insertion-excision system in prophage, 960 instinct, 189 instrumental learning, 218-223 see also conditioning, operant insular cortex, 344-345, 346 auditory units, 344 somatic units, 344 insulin, 531, 532 and NGF, 821-822 intelligence concrete, 179-180 formal operational, 180 human, 176-188 preoperational, 179-180 see also cognition Intensive Study Programs, v-viii interference theory, 166-167 proactive inhibition, 166-167 retroactive inhibition, 166-167 see also forgetting; learning intermediate zone, see mantle zone interneuron, 130, 411, 413, 420 brain development, role in, 67 crayfish, 399, 402-404, 402 defined, 409 ontogeny, 411, 413 origin, 65 phylogeny, 411 interneuronal interface thalamic, 465-469 interneuronal recognition glycomacromolecule role, 750, 758 internuncial neurons of cerebellar cortex, 419 intertubular canals, 845, 846, 847 intestinal contraction operant conditioning of, 220, 221 invertebrates central neurons of, 798-811, 799, 800 nerve-cell maps, 801 nerve ensheathment, 791 nervous systems of, 260, 276 neural conduction in, 791 neural transmission in, 720-721 see also insects ion carrier peptide, 870 solvation change, 869, 870 ion injection, 681-682 ion transport alkali-, 691ff membrane fluidity role, 703-704 mitochondrial, 830-831, 830 rate-limiting step of, 695 relaxation spectrometry for study of, 695 solvation and conformation changes, 869, 870 see also membrane; permeation IPSP (inhibitory postsynaptic potential), 452, 453, 458ff

alternation with EPSPs, 450, 461-462, 461, 462, 467, 468, 578, 578 attenuation, 462 mean rate influence on, 579 mitral cell membrane hyperpolarization and, 544 neuron discharge synchronization, role in, 460-462, 460, 461, 462 thalamic stimulation and, 463ff in thalamocortical afferents, 459 see also EPSP: PSP isocortex, 464-466 homology, 17, 22, 24 limbic system, dichotomy of function with, 341 neurons, 65, 66 phylogeny, 19, 22-25, 24 stimulus discrimination in, 345, 347 see also external striatum

L

L-ascorbic acid synthesis in birds, evolutionary trends, 31ff, 33 labor, division of, 44 labyrinthodonts, 28-29, 29 lactose (lac) genes, relative size of, 950 operon, 947-948 phenotypic complexities, 953 region of E. coli, 947ff, 947 repressor, 948-950, 950, 952, 952, 953 transport, 704 lactose operon, 947-948, 947 Land effect, 304 language, 181-182, 184, 302, 361-371 biological origins, 181-182 brain correlates of, 361-371 brain topography and, 362, 367 characteristics of, 181, 368-370 cognition and, 182-183, 264-365, 364, 365, 367-368 color recognition and, 182 concept formation facilitated by, 182-183 critical periods of learning, 292 development of, 181-182, 183, 291, 292 etiology, 365-366 evolution of, 45 "naming" adaptation, 45 neurological correlates, 363ff origin of, 45 recognition and, 366-368 second signal system of, 183 simian, 45 skills, dissociability of, 364, 364, 365, 365 sound patterns, processing of, 369 speech and, 364, 365

speech praxia, 365 stimulus-response (S-R) models of behavior and, 177 symbolic processes, 183 vocal system and, 357, 359 word-presence, 365 see also cognition; linguistics; speech; vocalization language capacity, 291 characteristics of, 368-370 ineradicability of, 365 vocal-tract structure and, 363 neuroanatomy and, 361-363 brain activity patterns and, 362, 365 brain size and, 361-362 see also speech language disorders, 363, 367 brain lesions and, 361ff, 367 cerebral dominance and, 362, 365 cognitive disorder similarities, 366-367 etiology, 365-366 language-specific computation, test of capacity for, 370 logorrhea, 365 symptom dissociability, 364-365, 364, 365 see also aphasia; cognitive disorders; speech disorders language knowledge, 370 defined, 364, 365 lateral geniculate body (LGB) degeneration in, 345 evoked potential in, 256, 256 glomerular synapses in, 431, 433, 433, 435, 441 presynaptic inhibition in, 433 recurrent inhibition in, 640, 642 response to inhibitory input, 640, 642 receptive-field inhibition, 640, 642 receptive fields, 638, 639 synaptic organization of transmission in, 638-642, 646 see also medial geniculate body lateral inhibition, 419 analysis by circuit theory, 389, 392 in flies, 399 of mitral cells, 562, 563 in olfactory bulb, 549 in peripheral sensory systems, 394 in retinal ganglion cell, 636-638 learned glandular responses, 218-223 learned responses electrical brain rhythms and, 224-243 learned visceral responses, 218-223 heart rate, 218-220, 219, 220, 221 homeostasis and, 222 intestinal contractions, 220, 221 reinforcement of, 218, 219-220 specificity of learning, 220-221 learning, 162, 193-194, 218-223 affective state and, 331, 332 biogenic amines and, 332, 324-336 memory and, 164 biochemical changes in neurons during, 278, 281-288 brain response patterns and, 295 brain rhythms and, 224-243 critical periods for, 292 disorders, 292 genetic differences and, 189 glandular, 222 innate propensities and, 194 instrumental, 218-223

memory consolidation and, 189 memory establishment following, 272-277 motor, 167 neural mechanisms, 260 norepinephrine release and, 333 observational, 191 perceptual, 171 phylogenetic comparisons, 194 protein changes in, 278-289, 283 skeletal, 218-220 specificity, 220-221 plasticity and, 162 S100 protein and, 285-286, 285, 286, 287ff protein synthesis during, 333, 823 RNA synthesis during, 823 self-preservation, role in, 193 stability and, 162 trial-and-error, 192-193 verbal, 167 see also cognitive development; conditioning; memory learning retention actinomycin effects, 273 protein synthesis effects, 272, 272 see also memory learning theories American, 177-179 education and, 185-186 Soviet theories, 183-184 stimulus-response theories, 177 see also cognitive development theory; Piaget learning set, 34 comparative development, 35 evolutionary trends, 34-36, 36 lemniscus, 11, 13 glomeruli and, 433 homology, 14 nerve fiber terminal patterns, 446 neurons, functional characteristics, 446 lemniscus, medial tactile-kinesthetic function, 605ff Lewis blood group fucosyl transferases and, 748 leucine incorporation into acidic protein during learning, 281-285, 284, 285 incorporation into neuronal protein during conditioning, 286-287, 287, 288 LGB, see lateral geniculate body ligand substitution in metal complexes, 687-688 ligand binding free energy of, 686, 686, 687 limb cortical representation of hind-limb, 606, 608, 608, 609, 610, 611 limb movements reflexive, misdirected, 117-118, 120, 121 visual deprivation effects, 321-322, 322 see also skin grafts limb transplant innervation, 112 mytotypic respecification, 154 urodele spinal cord and. 154 limbic system, 10, 314, 377-378 attitudes, influence on, 346-347 brain lesion effects, 377 bull-taming experiment, 377 electrical stimulation effects, 377 emotion, role in, 302, 339ff insular cortex, 344-345, 346

isocortical dichtotomy of function, 341 limbic cortex, 339-340, 341 limbic lobe, mammalian, 339, 340 morphology, 339-340, 341 nomenclature, 10 nonmammalian morphology, 10 olfactory impulses, 345, 346, 347 psychic functions, 347 serotonin in, 340 thalamic link to, 458 Limulus eye model, 392, 393 linguistics, 178 semantics, 369 syntax, 178, 369 transformational grammar, 178, 368-369, 369 see also language lipid hydrocarbon chain packing in, 702-703 in membranes, role of, 703 see also glycolipid; hydrocarbon chains lipid bilayers, 677-684 additives, effects on conductance, 682-683 antibiotics and, 682 bubbles, 679, 679 construction of, 680 field dissociation effect, 682 formation, 679-680, 679, 680 gateable additives in, 682-683 ion carriers in, 682 ion transport in, 682, 869 microvesicles in, 680 nonlinear conductance, 681ff potassium ion permeability, 682 proton carriers in, 681 study of, 678ff structure of membrane fluid regions, 701 lizard (Iguana iguana) head-nodding display, 350, 350 lobster (Homarus americanus) walking-leg nerve fiber, paramagnetic resonance in, 698, 700 walking-leg nerve fiber, membrane fluidity, 701 logorrhea, 365 long-term memory, see memory, long-term lordosis reflex castration effects on, 198 estrogen effects on, 199 suppression by hormones, 200 testosterone effects on, 199 see also sexual behavior lysogenization by bacteriophage lambda, 955, 955, 956 lysozyme-inhibitor complexes, 904, 904 binding in, 904 conformation in, 904 hydrogen bonds in, 904 specificity in, 904

Μ

mDNA, see DNA, mitochondrial macaque, see monkey Mach band, 394 macrodeterminacy in CNS development, 54 see also microdeterminacy macroglia, 63 macromolecular nets, vi ff macrotetrolides

chemical structure, 691 see also monactin mammals fetal behavior in, 149ff neuroendocrine transducer cells in, 530-538 phylogeny of, 29-30 see also individual species mammals, placental phylogeny, 30, 30 man evoked potential, conditioning of, 250, 250, 252, 252 evolution, 44-46 maturation rate, 42, 44 object use, 44 nonverbal communication, 357-358, 358 phylogeny, 42ff social behavior, 44-45 stress, EEG patterns during, 236-239 see also Australopithecus: Homo erectus; primates mantle zone, 63, 64 marginal zone, 63 masculine social behavior androgen effects, 201-205, 202, 203 gonadectomy effects, 201, 204 neural structure influence on, 205 master genes, see gene, master mathematical models dendritic branching, 552, 553 neurons, 552-554, 553, 554 maturation, 176, 184, 293 cognitive development and, 180, 184, 290 eye movements and, 184 genetic determinants, 293 genetic "switching," 294 hormonal influences, 294 language development and, 182, 291 see also behavioral ontogeny Mauthner neurons circuit system, 393, 394 of fish, 398, 398, 403 maze-learning, 291 genetic factors, 189 medial geniculate body glomerular synapses in, 433 see also lateral geniculate body medulla oblongata, fetal cell proliferation and migration, 101 melanocytes, 62 melatonin, 531, 532, 535 biosynthesis in mammalian pineal organ, 534 neural and photic regulation of synthesis of, 534, 535 norepinephrine effects on, 535 membrane bilayer models of, 678-681, 679, 680, 869 binding sites, 704 circular dichroism in, 868 cyclic antibiotics and, 682 DNA in, 867 excitation in, 678, 685, 708-713, 869-870 fluidity of, 701-705 gateable additives and, 682 hydrophobic regions of, 697, 697, 701 information transmission in, 681, 870 ion carriers in, 678, 681, 682, 685-696, 869, 870 ionic theory of, 708 lipid bilayers in, 677-684 lipid-protein interaction in, 683

lipids in, 867, 869 matrix of, 867 mitochondrion, 677 molecular components of, 867, 868, 869 molecular motion in, 697ff, 701 molecular organization of, 867 myelin, 677 and optical rotatory dispersion, 868 organization of, 867 permeation of, 678, 703 protein in, 816, 867 RNA in, 867 spin labels in, 697ff, 869 structure of, 704, 704, 867-869, 868 systems, 867-870 transport in, 704-705 two-stable-states theory of, 707 types of, 677 "unit," model of, 867 variations in, 677 see also biological membranes; lipid bilayers; mitochondria membrane excitation methods of studying, 858 two-stable-state hypothesis, 858 membrane fluidity biological functions, 703-705 molecular origin, 701-703 perpendicular transport and, 703-704 membrane matrix molecular organization, 867-869 pump, carriers, and other membrane effectors, 867, 868 membrane models of neurons, 554, 554 membrane polyanions role of in electrical rhythm, 239-240 membrane potential, 583 EPSP effects on, 583, 584 of mitral cells, 543-544 neuroglial, 792 membrane systems, 867 memory, 342 amine role in, 329-333 amphetamine effects on, 273, 273 biology of, 272-278 criteria for study of, 164 epileptic seizure and, 342 evocation by brain stimulation, 173 extracellular space in brain and, 865 formation, 272 heterosynaptic facilitation and, 263-264 human, 164-168, 168 learning and, 164 neural mechanisms, 172-173, 330 neuronal mechanisms, 260, 270 nomenclature, 164 normal, 163-176 pathological, 163-176 processes, 272-277 processes, human, 164-168, 168 storage mechanisms, 275-276, 276 study of, 164 temporal parameters, 264 time and, 164 vestibular, 264-265, 265 see also forgetting; information retrieval; learning memory, long-term, 272-274, 277 acetoxycycloheximide effects, 272-273, 273 arousal role, 273

conditions for, 273 corticosteroids and, 273 defined, 164 protein synthesis, dependence on, 272-273, 277 see also memory, remote memory, pathological, 168-173 memory, primary, 166-168, 172 in anterograde amnesia, 169, 173 in motor skills, 170 in retrograde amnesia, 171 memory, recent defined, 164 memory, recoded, 165-166 memory, remote defined, 164 memory, secondary, 166-168, 170, 172 in anterograde amnesia, 169, 173 in retrograde amnesia, 171, 173 memory, sensory, 164-166 in anterograde amnesia, 169 auditory mode, 165 defined, 164 visual mode, 165 memory, short-term, 189, 272-274, 277 acetoxycycloheximide, effects, 272, 272, 273 defined, 164 see also memory, recent memory, tertiary, 167-168 in retrograde amnesia, 171 memory, vestibular, 264-265, 265 memory consolidation learning performance and, 189 Mendelian genes, 983-985 mentation, 346 mesencephalon, see midbrain (mesencephalon) mesenchyme, 62 epithelio-mesenchymal interactions, 80 messenger RNA, see mRNA (messenger RNA) metaphase arrest, 63 micodeterminacy in CNS development, 54 metal complexes ligand substitution rates in, 687-688, 688 stability constants, 687, 688 methanol field effect relaxation of Na+ -murexide complex in, 691 rate and stability constants of alkali complexes in, 689, 689 as solvent for carriers, 689 methodology autoradiography, 62, 64, 74, 103, 122, 1005 behavior measurement, 36-37, 248-249 circuit theory, 389 coincident-current selection techniques, 454 EEG pattern recognition and analysis by computer, 234ff, 236 electroantennogram (EAG), 512, 516 field analysis, 444 language-specific computation, test of capacity for, 370 membrane excitation, study of, 858 neural circuit mapping, 389 neuronal electrical activity, recording methods, 648-649 neurophysiological research, basic approaches 569-570, 570, 571 radioactive labeling, 64ff, 66, 68, 69 radioisotopic analysis, 843, 844, 846 relaxation amplitude method for enthalpy, 691-692

relaxation spectrometry, 695 sensory physiology, 494 spike-train analysis, 572-573, 595-596, 648-660 stimulus-response matrix, 571, 573, 573 subcellular fractionation, 761-764 synaptic staining procedures, 735-736, 736 see also electrical brain stimulation; electron microscope; mathematical models; nerve tissue culture; statistical techniques; systems analysis microtubules, 854 amino-acid composition of protein in, 855, 855 in axoplasmic transport, 854 neuronal, 845-848 in oligodendrocytes, 788, 790, 791 synaptic vesicle contacts, 875-876 midbrain (mesencephalon) homology, 16-17 tectum, visual pathway function, 377 vocalization, role in, 363 mind, vii, 486, 493 miniature end-plate potential, 715 acetylcholine release and, 715, 774 neurotransmitter release and, 774, 775 mitochondria and bacterial protein synthesis, 828-829 biochemical differences among, 814 chemical coupling in, 832, 833 chemiosmotic process and, 833, 833 conformational-coupling hypothesis, 834 DNA in, 827, 828 electron transport, 831-832 energy-coupling modalities, 831-832, 832 evolutionary origin, 829 functions, 874-875 gene products of, 828 genetic apparatus, 828, 829 growth, 827 ion transport, 830-832, 830 membranes, 678, 718, 718, 829-830, 830, 835-836 membranes, metabolic exchanges across, 830-831, 830 in myelinated axons, 844 neurofunction of, 827-839, 874-875 origin, 678 protein, 829 protein synthesis, 813-814, 813, 828, 829, 835 ribosomes, 828 RNA, 828 separation from myelin and glial fragments, 763 transport systems, 830-831, 830 uncouplers, effects of, 681 see also DNA, mitochondrial; oxidative phosphorylation mitochrondria, neuronal in axonal flow, 844, 845, 847 breakdown, 842, 845, 848 enzymes of, 845 mitochondrial DNA, see DNA, mitochondrial mitral cells axon, 541, 544, 546 axon, soma, and dendrites, 554, 554 dendrites in, 539-541, 544, 546-549, 546 excitation and inhibition of, 541-544, 542 hyperpolarization in, 544 impulse generation in, 542, 543 inhibition, 562 lateral inhibition in, 562, 563 model of, 554

of olfactory bulbs, 539, 540, 549, 550 population, 557 simulation of antidromic activation in, 554-555 synchrony and symmetry of, 555, 555 voltage transients from, 558 modularization of cortical pyramid, 448 molar behavior, 178 brain-wave modifications and, 254, 255 molecular biology approaches to neurophysiology and, 858-866 molecular genetics contributions to neuroscience, vi molecular motion in biological membranes, 697-706 molecular neurobiology, 675-879 molecules, replicating, 927ff mollusks central neuron functions in, 808-810 ganglionic neurons, 54 see also Aplysia monactin, 691-693, 692 field-effect amplitudes, 694 murexide absorption and, 691, 692 monkey communication by, 352ff, 355, 356 destriate, and vision, 322 fine-structure development, 130-139 genital display in, 351ff motor behavior onset and fetal growth, 131 New World, 41, 352 Old World, 41, 352 phylogeny, 40, 42-43 septal stimulation, 346, 347 topological mapping of, 606ff, 608ff vocal repertoires, 352ff, 353, 354 see also apes (Pongidae) monkey embryo motility, spontaneous, 130, 131 motor-neuron neuropil, synaptic bulbs in, 134ff, 134, 135, 136, 137 reflex movements, 130, 131 spinal-cord neurogenesis, 130, 135 molecular vision, 471 deprivation effects on visual-motor coordination, 321, 321, 322, 323 response to horizontal movement, 480, 480 Moody-Parriss model, 497-498 morphogenesis, 615 brain, 58 cell adhesiveness role in, 126 CNS, 58 genetic control, 126 mossy fibers, 411, 414-415, 418-419, 427, 429 and cellular glomerulus, 412 functional properties, 415 schematic of, 417 mossy rosette, 427, 440 excitation of granule cell and Golgi cell dendrites, 429 motility, embryonic analysis of, 130, 131 cyclic nature of, 142-143, 142 integrated, 149 nonreflexogenic, 141-144, 148, 148 onset, 130, 131 random, 148 sensory input, 143-144 spontaneous, 141-144, 147, 148 stimulated, 149-150 in vertebrates, 141-151

motivation plasticity of, 207-208 prepotent responses and, 214 stability of, 207-208 see also drive state motivational systems stability and plasticity of, 207-217 history of, 208 motoneuron, see motor neuron motor coordination, 177-178 motor end plate, 715, 716 see also miniature end-plate potential motor neuron of crayfish, 399, 410, 402-403 differentiation, 131, 132 epithelio-mesenchymal interactions, 80 firing pattern and synaptic noise, 624 of flies, 399, 400 function-specific groupings, 109-110 membrane properties, 859 of nonmammalian CNS, 9, 13 subspecification, 59 synaptic potentials in, 862, 863 see also nerve-muscle interaction; reflex motor pathways, 17-18 establishment of, 111 motor periphery differentiation, 110-111 connections with center, 111-112 motor skills, 169-170 motor systems, 17-18 nerve pathways, 17-18 nonmammalian, 9, 18 vertebrate, development of, 108-116 movement control of, 318, 319, 321 movement perception, 308 in insects, 501, 502, 509 multiplexing of thalamic output, 452-453, 456 murexide, 689, 690-691 field-effect amplitudes, 694 spectral properties, 689-690, 689, 690 spectrophotometric titration of, 689, 689 Musca, see fly muscle antagonistic, generation of drive for, 393, 393 homonymous, homologous response to, 109-110 muscle fiber contraction times, 111 differentiation, nerve-dependent, 110-111 "fast" and "slow," 111 innervation, 859, 862 skeletal, motor axons, 112 muscle spindles firing patterns, 623, 623 spike frequency and output, 667, 668 muscle-nerve interaction, 81, 153ff mutation, 977, 979 alteration in gene family size by, 985 ribosome alteration by, 915, 916, 916 mychronogram, 155 myelin fluidity, 701 formation, 788, 790 metabolic properties, 787-791 protein, 816 structure, 867-868 myelin sheath, 62, 677-678, 787ff axolemma contacts with, 787, 788

axon nourished by, 791 extracellular space and, 787, 788 formation, 112 function, 135-136 neuroglial delay in acquiring, 135-136 oligodendrocyte relationship, 788, 789, 790 specializations, 787 *see also* neurilemma; Schwann cells myotypic specification, 109, 110 in limb transplants, 154 in neurons, 155

Ν

natural code defined, 574 neural change and, 577 natural selection, 965, 966 neocortex, see isocortex neopallium, see isocortex nerve activity structural changes during, 707-714 nerve cell, see neuron nerve endings, 723 nerve fiber, 17-18, 59 adhesiveness variations, 126 command fibers, 402-404, 403, 408, 490ff differentiation of muscle fibers by, 110-111 fasciculation, 85, 89, 111-112 giant, of crayfish, 399, 401, 402-404 growth, 123ff pathfinder, 111 peripheral nervous system, 62 optic tract, 15, 639 regeneration, in optic nerve, 120 sensory, 16-17 size, neural transmission and, 597-598 space constant, 597 see also axon; dendrite; nerve pathways nerve fiber connections after eye rotation, 120-122 chemotropism role, 123ff CNS, sensory, 117-118 eye-brain, 118-123 functional validation, 126-127 genetic determination, 126-127 growth and, 123-126 limb-spinal cord, formation, 112 mechanisms, 123-126 nonspecific afferentation, 16-17 regenerated, 118, 120, 123 retinotectum, 118-122, 123 sensory, rearrangement of, 118 skin graft, 117-127 specification, 117-127 specificity of, 861-862, 862, 865 nerve-fiber growth actinomycin-D effects on, 821, 822 contact guidance, 111 in vitro, 85, 86 mechanisms, 123-126 nerve growth factor (NGF) effects on, 820-821, 822 nerve growth factor (NGF), 62, 80, 84-86, 87, 89, 816 fiber outgrowth and, 85-86 inhibition, effects in ganglia, 816-817 insulin and, 821-822 macromolecular structure, 817-820 mechanisms of action, 820-821 neuron survival and, 104

phytohemagglutinin (PPHA) and, 822 as regulator of gene expression, 816ff RNA synthesis and, 821-822, 822 in spinal ganglia, effects on glucose metabolism, 820. 821 see also culture media; nerve tissue culture 7S nerve-growth factor, 817-820, 817, 818 enzymatic activity of subunits, 818, 818 molecular size and composition of subunits, 819, 819 nerve pathways, 11 frequency-specific, 452 motor, 17-18, 111 nonmammalian vertebrate, 9 sensory, 13-16 nerve regeneration fiber connections, 118, 120, 123 selectivity in, 154 nerve terminals isolation of, 761, 763 mossy-fiber endings, 761, 763 neurotransmitter synthesis in, 772 presynaptic, resistance to breakdown by liquid shear forces, 761, 762 nerve tissue androgen alteration of hormone sensitivity in, 201, 205 nerve tissue barriers, 784, 786-787, 786 perineurium as, 786 nerve-tissue culture, 83-84, 95ff bioelectrical activity in, 85, 89, 92-94, 94 cell, dissociated, 85-91, 94-95, 97 cerebral cells, 94-95, 96, 98 CNS, 91-95 cytotypic and organotypic maturation in, 84, 89, 92 spinal sensory ganglia, 84-85, 87-88, 90-93 see also cell culture; culture media; explant culture nerve-muscle interaction, 81, 153ff nervous system autonomic, 218-223 chemoaffinity and organization of, 120ff chemotaxis, 123, 126 coding in, 569-671, 630 communication in, 569-671 development of, 51-157 embryogenesis, sensory input lack, 108 embryonic, topographic mapping in, 108 evolution, 7-25, 26ff functions, 375-383 gene expression in, 812-827 morphogenesis, 126 neuroendocrine interaction, 519ff, 519, 526 nonspecific activating, 377 optical data in, 494-511 plasticity in, 260-271, 660 simple system advantages and disadvantages, 260 specific proteins in, 815 see also central nervous system; peripheral nervous system network, fibrous contact guidance by, 111 network element, abstract, 384, 384 see also circuit theory neural analogue (electronic), 601, 601, 602 PST histograms of response, 601, 602, 603 neural centers, shaping of, 62-72 neural change, 576-577 natural codes and, 577

spatial and temporal components of neuronal response to, 576ff, 576 neural codes, 254ff behavior relevant, 254ff candidate code, 254, 660 spike-train parameters as, 665 of spike trains, 587-588 validation of, 254, 256 neural coding, 25, 569-671 anatomical connectivity and, 256 evoked potential and, 243-259 spike-train frequency and, 624 stimulus-selective, 653ff, 660 temporal, spontaneous electrical activity and, 256-257 voltages in brain and, 255 neural crest cell migration, 126 see also neurogenesis neural development, 53-61 neural excitation anionic sites on membrane and, 240 protein and, 296 two-stable-states theory of, 707-708, 858 neural impulse, see spike neural impulse trains, see spike trains neural mechanisms of learning, 172, 173, 343-346 neural network, 389 models, 389, 391, 393 operations, 389, 391 simulations, 389, 391 transcription and differentiation, 1011, 1012 neural network, self-assembling specificity, 996 neural operations, 397-409 neural plates neurogenesis of, 56, 58, 62, 63, 108 origin of, 62-63 neural subsystems, 375-377, 384-396, 486-494 command-and-control in, 489-491, 491 concepts of, 384-396 interactions in, 384-386 physiological operations and, 375-565 thalamic, 458-470 see also circuit theory; systems analysis neural tissue central, 91-95 development in vitro, 83-99 explant cultures, 84-85 dissociated cell cultures of, 85-91 peripheral, 84-91 neural transmission, 597, 603-604, 630, 661-671, 858-859 all-or-none spike-train role, 597, 598 analogue signals role, 597ff by constant signals, 598ff, 599, 600 cyclic stimuli and, 600-601, 602, 603, 604 constant signals and, 598-600, 599 distortion in, 601, 604 in dorsal spinocerebellar pathway, 617-629 by DSCT neurons, 624-625 encoder model of, 666 frequency-independence of transfer function, 618, 670 impulse frequency demodulation, 663-666, 664 information theory applied to, 624 inhibition effects, 625-627, 626, 627 input frequency effects, 664 input-output relationships, assessment of, 662-663. 663 interface role in, 669-670

invertebrate, 720-721 low-pass filter, 663-666, 663-666 multiple channels and, 668-669 nerve fiber size and, 597-598 neuronal variability and, 601, 604 parallel input channels, 667-668, 668 random spike trains and, 668-699 rate of, 600 single channel, 666-668, 668 spike-train density and, 600-601 spike-train types and, 666ff stimulus duration and, 600, 600 synaptic mechanisms, 620ff systems analysis and, 661-662, 669 vertebrate, 721-722 neural tube basal plates, 80 fine structure, 63 histogenesis, 62-63 neurogenensis, 56, 62-64 spongioblasts, 63 see also neural crest neuraminidase, 750 neurilemma, 62 see also myelin sheath; Schwann cells neurite differentiation of, 802-803 distribution within the neuropil, 801-802 integrating segment, 803, 804-806 link segment, 803-804, 806, 807 neuroanatomy language and, 361-363, 362 neurobiology molecular, 675-879 neuroblast, 63-65, 67, 69, 71 axon formation, 70 behavior, 69 dendrite formation, 69, 70 differentiation, basal plate, 109 migration, 69 proliferative gradients, 70 neuroblastoma electrical excitability in vitro, 859, 860, 861 neurocoel, 63 neuroembryogenesis behavioral ontogeny and, 289-290 neuroembryology, 100-102 cell nomenclature, 52fn history of, 51-52 neuroendocrine communication, 519ff, 519, 526 aminergic mediators, 525-526 hypophysiotropic factors, 525-526 neurochemical mediation, 521ff, 525 neuroendocrine transducer cells, 527, 530-538, 530 see also chromaffin cells; juxtaglomerular cells; hypothalamic cells; paraventricular hypothalamic nuclei; pinealocytes; supraoptic ĥypothalamic nuclei neuroepithelial zone, 63 neural tube, 52ff see also names of individual zones, e.g., mantle, marginal, subventricular, ventricular neuroepithelium, optic vesicle cytodifferentiation, 122-123 DNA synthesis, 122-123 generation time, 122-123 neurofilaments, 845, 848, 854 amino-acid composition of protein, 855, 855 axoplasmic transport, role in, 854-855 neurogenesis, 53ff, 60, 62ff, 69ff, 108ff, 126

chemoaffinity of neurons, 120 displacement, 104, 104 ganglia, retinal, 120-122 microdeterminacy vs. macrodeterminancy, 54 pathways in developmental dynamics of, 57, 60 retrohippocampal formation, 65 spinal cord, 130-140 of synaptic connections, 104-106 visual system, 120-123 see also neuron, differentiation neuroglia, 782, 782fn, 842 antigen composition, 279ff development, 782 differentiation, 64, 130 extracellular space and, 784, 785, 787 function, 782-797 gantlet concept of function, 792-793 histogenesis, 63, 67, 69 ionic environment, 787 neuronal interactions, 792-795 neurons and, 782, 785 proteins in, 278-279 resting potential, 792 ribosomes in, 813 sheathing in, 135, 783, 784ff, 785, 787 structure, 782-797 see also astrocyte; glial capsule; glioblast; macroglia; nerve ensheathment; oligodendrocyte; Schwann cells neurohemal organ, 521, 777 neurohormones, 521, 768-782 intrahypophyseal functions, 521 neuroendrocrine communication and, 526 released by neurosecretory neurons, 779 see also oxytocin; vasopressin neurommatidia see optic cartridges neuron activation, changes after, 330-331 afferent, development of, 131 analysis of, 649-652 antigen composition, 279ff astrocytic processes and, 792, 793 binocular gate, 482 biochemical changes during learning, 278, 281-288 birefringence, 710-712, 710, 711 central, 801 chemoaffinity, 120 cholinergic, 765ff chromatolysis, 801 coding, 569-586 command neurons, 489, 490-491, 865 common excitation effects, 592-594, 593 communication properties, 530-531, 569-586 connections, 116-129, 861-862 depth distributions of potential in, 558-559, 559 dendritic structures of, 860-861 differentiation sequence, 130-131 differentiation vs. proliferation, 841 dynamics, 840-850 efferent, development of, 131 electrical activity, recording methods, 648-649 endocrine action on, 78 information storage in, 260-261 in frog tectum, 378-379 functional adaptation, 843 functional association of, 648-661 functional plasticity, 862-864 ganglion, excitation of, 593 glycoprotein transport in, 753, 754

hippocampal, specific activities of, 284, 285 histograms of, 651, 654-658 identification by Procion Yellow injection, 801, 804, 807 information content, 378ff information storage sites, 260-261, 264-270 information theory on, 572ff information transfer, 531, 661ff, 667-669 information transfer function, 666, 667 information transmission, 572-583, 597-598 inhibition, effects of, 625-627 inputs and outputs, 530 interaction, stimulus effects on, 653-658, 656-658 interaction, temporal structure of, 658-660, 659 interconnections, 652-653, 653, 861-862, 862, 863 intracellular recordings of, 648, 649 invertebrate, 676, 798-811 ionic environment, 787 pyramidal, protein of, 284, 285 mathematical models, 552-554, 553, 554 maturation, 782 meaning of signals in, 378, 379 membrane model of, 554ff, 554 methods of recording electrical activity, 648-649 modifiability, 127 mollusk and crustacean ganglia, 54 neuroglia and, 782, 785 neuroglial interactions, 792-795 organelles, 827ff organic anions in, 768 origins, 70 pathways between, 653 presynaptic and postsynaptic, cross-correlation, 591-592, 592 proteins in, 278-279 protein synthesis in, 841-845 radioactive labeling, 64 recordings of, 649ff, 650 regeneration, 840, 843 "sameness," 378-379 second-order, 620ff, 620, 621, 625-627, 626, 627 self-re-excitation, 267ff sensory, 94, 117-118 sheathing onset, 135-136 signal transmission between, 617-629 simplified models of, 553, 553 small molecules in, 768-782 soma and spike initation sites, 798, 808-810 soma-dendritic complex, 805 soma isolation from bioelectric activity, 805, 808-810. 808 spatial averaging of, 601-603 as spike-train analyzer, 577-582 stimulus duration of, 600 structure, physiological role and, 859-860 types, defined, 130 vertebrate and invertebrate, 798-811, 799, 800 see also axonless cells; circuits; Mauthner neuron; motor neuron; nerve fiber; nerve fiber connections; neural conduction; neurogenesis; neuron specification; neurosecretory neuron; Nissl bodies; pacemaker neuron; sensory neuron neuronal circuitry, 487, 563 circuit theory, applicability, 389, 391, 393 decomposition, 387-389 development, 131-136

for drives, 291 feedback loops, 54 functional readiness, 131 hippocampal role in cerebral interactions, 231-232, 233 mapping methods, 389 maturation and, 293 nonspecific afferentation, 16-17 synaptic closure, 132 see also nerve fiber connections; reflex neuronal conduction birefringence, voltage-dependency of, 711-712, 711 disulfide bonds and, 718-719, 719 entropy changes during, 709-710, 709 fluorescence emission changes during, 713 invertebrate, 791 ionic theory, 708, 708 light intensity change during, 710-711, 710 light-scattering changes during, 712-713, 712, 713 temperature changes during, 709, 709 structural change during, 707ff, 713-714 neuronal discharge, see firing neuronal discharge pattern, see firing patterns neuronal hypertrophy, 843 neuronal junctions, see synapse neuronal membrane, 260-261, 676 "accommodation," 859 axoplasmic transport in, 853-854 binding sites, 701 cerebral, structural limits, 239-240 divalent cations and excitation, 240 entropy changes, 709, 710 excitability, 710-712, 710, 711, 869-870 excitation, 685 information storage and, 240 input-output relations, experimental approaches, 662-663, 663, 669 ionic theory, 708 linear input-out relationship and, 618 permeability, molecular mechanisms of, 708 potassium channels, 708, 709, 714 sodium channels, 708, 709, 714 spin-label motion, 701 stable-states theory, 707-708 structural changes during conduction, 707ff, 712, 713-714 surface, polysaccharides on, 747, 748 see also neuronal conduction; biological membrane neuronal microtubules, see microtubules neuronal mitochondria, see mitochondria. neuronal neuronal modulation, 110 see also neuronal specificity peuronal nets transcription and differentiation, 1011, 1012 neuronal organelles, 842, 844, 845, 846 see also mitochondria; neurotubules; neurofilaments; intertubular canals neuronal protein, see protein, neuronal neuronal specificity, 59ff, 62, 110, 116, 127, 152-156 degrees of, 117, 127 genetic determination, 117 mechanisms, 156 peripheral, of cutaneous nerves, 117-118, 121, 122 subspecification, 59 see also nerve fiber connections; neuronal

modulation neuronal transport mechanisms fast traffic mechanism, 847, 848 neuroplasmic flow, 846, 847 retrograde message transfer, 848 see also axonal flow; neuroplasmic flow neuronal waves amplitude distribution studies, 225-226 neurobiosynthesis epidermal growth factor (EGF) and, 822 gene activity, 823 gene expression and, 812ff, 873, 874 hormones and, 823 mitochondria and, 827-839 nerve growth factor (NGF) and, 817ff, 817-820 organelles and, 874 protein products in, 815-816 of specific proteins, 812-816, 816, 874 in vertebrates and invertebrates, 798ff, 799-800 see also gene; mitochondria neurophysins, 779 neurophysiology, 486 experimental approaches in, 569-570, 570, 571 information theory application to, 572-574, 573, 574 molecular biological approaches to, 858-866 operations research and, 380 revolution in, 376 neuropil cervical motor, macaque embryo, 136 crayfish, 399 intersection of fibers in, 391 neurite distribution within, 801-802 neuroglial processes, 136, 138 synaptic bulbs in, 136 neuroplasmic fast transport, 677 neuroplasmic flow, 677, 840ff, 846-847, 860, 875ff axonal material in, 848 chemomechanical energy coupling in, 875 fast, 875 mechanisms, 847 microtubules and, 786 mitochondria in, 844-845, 847 peristaltic contractions and, 875 proteins and, 875 Schwann cell role, 847 slow, 875 synaptic functions and, 873 velocity, 846 see also axoplasmic transport neuroscience, vi genetics and, 925 Neurosciences Research Program (NRP), v, vii Intensive Study Programs, v-viii neurosecretion, 521ff, 777ff classical concept of, 521-525 Dale's law, 779 defined. 777 exocytosis as mechanism for, 776 neurotransmission and, 774, 777, 778 into portal vascular system, 777, 778 into systemic circulation, 778 glandular secretion and, 779 in vertebrate hypothalamo-neurohypophyseal region, 777-778, 778 neurosecretory neuron A-type fibers, 522 B-type fibers, 522, 526 control of endocrine cells by, 521 diagram of, 523 neurohormone release mechanism, 524-525

neurohormone release sites, 524-525, 524 see also neurohormones neurotransmission glandular secretion and, 774 neurosecretion and, 774, 777, 778 structures related to, 715 neurotransmitters, 326, 530-531, 533-535, 768-782, 770, 771 acetylcholine, 329, 770ff adrenalin, 770 at adrenergic synapse, 325 aminobutyric acid, 770 biosynthesis, 771-773, 772 catabolism, 776-777 chemical structures, 771 dopamine, 770 dynamics, 872 glutamate, 770 glycine, 770 5-hydroxytryptamine, 770 inactivation, 777, 778 identification, 761 neuroendocrine integration and, 521, 524 neurohormones and, 526 neurosecretion and, 778 norepinephrine function as, 326-327, 329, 770 output from disused nerves, 864, 864 physiological functions, 769-770 postsynaptic receptors for, 770-771, 779-780 quantal release, 715, 720, 723, 725, 774 receptor site, interaction with, 779 storage in synaptic vesicles, 734, 774 transport system properties, 777, 777 see also Dale's law; neurohormones neurotransmitter release, 773-776 exocytosis hypothesis, 726, 775-776, 776, 872-873 mechanisms, 774, 776, 872-873 motor endplate potential and, 774, 775 neurotubules, 845-848 neurulation, 62 NGF, see nerve growth factor (NGF) Nissl bodies, 806, 809 differentiation of, 134 nodes of Ranvier myelin and, 787, 788 saltatory conduction, 722 nomenclature brain cells, 52fn limbic system vs rhinencephalon, 10 memory, 164 neuroembryology, 52ff neuroepithelial zone, 52ff neurons, 130 peripheral nervous system, 73 spinal cord cells, 52fn synaptic, 771 noradrenaline, see norepinephrine norepinephrine, 531-534, 532, 769, 770, 771ff amounts in brain, 327, 329, 331 AMP effects, 333 appetitive behavior, induced by, 329 arousal and, 329 changes in endogenous, 328 deficiency in brain and depression, 328 effects on melatonin synthesis, 535 electroconvulsive shock and, 328, 328 emotion and, 327 interneuronal distribution in sympathetic adrenergic neuron of cat and rat, 773 metabolism, drug effects on, 327, 328, 333

neurotransmitter function, 326-327, 329 rage and, 327 storage in adrenergic synaptic vesicles, 773, 776 storage in large granular synaptic vesicles, 734 storage in presynaptic vesicles, 325 transport, 854 turnover in brain, 327, 328, 328 norepinephrine release appetitive stimulation and, 328 in central nervous system, 327-328 learning and, 333 nerve stimulation and, 325-326, 326 synaptic, 326, 327 norepinephrine synthesis electroconvulsive shock simulation of, 327-328 nerve stimulation effects, 326 rate, 325, 325 in sympathetic nerve endings, 325, 325 sympathetic nerve-impulse activity and, 325, 325 tyrosine hydroxylase role, 325 notocord, 58, 62 nuclear double membrane, 677, 677 nucleic acid protein interaction, 901-912 nucleoprotein, 1000, 1003 nucleotides purine, 909, 909 pyramidine, 909 nucleotide sequences serial repetition in duplex DNA, 991, 992 nucleotides interaction with ribonuclease, 907, 907, 908, 908, 909, 909, 910, 911 nucleus reticularis thalami, 451 as a frequency sensitive gate, 452 nystagmus, 264ff labyrinthectomy effects, 265 optomotoric, 264-265, 265 see also afternystagmus

0

object use, 44 odorants acceptors, 514, 516 molecule transfer, 516 see also insect olfaction; pheromones olfaction chemoreception and, 511ff see also insect olfaction olfactory bulb anatomy, 539-541 as cortical system, 539-552 functional implications of neuronal interactions in, 547-550 mitral cell excitation and, 541-544 neuron differentiation sequence, 139 neuronal interactions in, 546 neuronal pathways and connections in, 545, 546 neuronal systems in, 544, 546-547 neurons, origin of, 64-65 organization similarities to retina, 549, 549, 550 potential divider effect in, 555 punctured symmetry, 555 in rabbit, 540, 542 repetitive responses in, 545 rhythmic potentials in, 549 self and lateral inhibition in, 549

synaptic responses in, 545 synchrony and symmetry, 555 theories on, 552ff olfactory nerve fibers, 539-541 olfactory receptors in Bombyx mori, 511-518 olfactory system nonmammalian morphology, 8ff olfactory tract, 539, 541 oligodendrocyte, 788, 789, 790 microtubules in myelin-related cytoplasm, 788, 790, 791 ommatidia of fly, 494-496, 495, 500, 501, 505, 509 see also rhabdomeres ON/OFF mechanisms, 491-492 ontogeny behavioral, 129-140, 188-196 neuronal specification, 152 synaptic, 129-140 operations research, see systems analysis optic afferent, 431, 433 optic cartridges of fly's compound eye, 500, 501, 502, 509 optic chiasm retinocerebral pathways and, 472 optic nerve adhesiveness of fibers, 126 connections, selectivity of, 123 fiber growth, 122 regeneration, 120, 123, 154 specification of connections, 122, 156 optic radiations, 342ff, 343, 345 Meyer's loop, 343, 343 optic tectum, 70 cell specification, 756ff, 757 function, 15 intracentral connection, 59 regenerated nerve fibers in, 154 retinal connections, 120-122, 123, 124, 756ff, 757 "sameness" neurons in frog, 378-379 optic tract nerve fibers, 639 optic vesicle cell differentiation, 122-123 DNA synthesis, 122-123 neuroepithelium, 122-123 optical data uptake, transduction, and processing, 494-511 optical ganglion lamina of fly's compound eye, 500, 503, 509 optical illusions, 304, 312-313 ambiguous figures, 312, 314 brightness contrast, 304, 305 complementary images, 307 contour direction, 306 Frazier "spiral," 310, 311, 313 Helmholtz's checkerboard, 319, 319 Land effect, 304 moiré figure, 311, 313 of motion, 308, 311, 313 Necker cube, 314 self-luminous objects, 308 simultaneous stimulation and, 306 stroboscopic illumination and, 308 visual noise effects, 306, 307, 309 see also afterimages; perceptual anomalies optical rearrangement, see visual rearrangement optical representation in fly's compound eye, 500-501

optomotor responses of fly, 498-499, 501, 505, 509 organismic psychology, 176-177 behavior theory and, 181 cognitive growth, 179 see also Piaget, Jean organotypic maturation, 84, 92 see also fasciculation orientation monocular deprivation and, 323 scotopic vision and, 321 visual rearrangement effects on, 320 ovariectomy hormonal changes, 199 overflow-preventing system in cerebellar cortex, 419 owl optic tract, 22 Wulst region of brain, 21, 22 see also avian brain oxidative phosphorylation, 831 chemical-coupling hypothesis, 832-833, 833 chemiosmotic hypothesis, 833-834, 833 conformational-coupling hypothesis, 834-835, 836-837, 838 uncoupling in mitochondria, 681 oxytocin, 532, 779, 779

pacemaker neurons plastic properties, 265, 266-267, 267, 268, 269 packing geometry of proteins, 902-904 of ribonuclease, 905 paleontology, 40, 45 see also fossils pallial mantle, see cerebral cortex . Panum's fusional area, 472, 479, 482 Papez circuit lesions and anterograde amnesia, 172 parallel fibers in cerebellar cortex, 411, 413 inputs from, 415-416 Purkinje cells and, 418, 419, 422-423, 422 synapses of, 416, 417 tonic activation in, 419 parallel processing of thalamic output, 464-465, 465 in thalamus, 456 parallel sensory systems, 377 lemniscal-ventrobasal pathway, 377 spinothalamic-posterior thalamic group pathway, 377 visual pathway, 377 paramutation, 963 paraventricular hypothalamic nuclei, 532 parenchymal cells of pineal organ, see pinealocytes pars intermedia endocrine effector cell innervation, 520, 522, 526 partial replicas of 2-micron subunits, 1005, 1006, 1007, 1008, 1009. 1010 pathfinder fibers, 111 pathological memory, see memory, pathological pattern generation in CNS, 380, 381 pattern generators arthropod, 399-408 central, 397-399

in fly, 399 in grasshopper flight control, 397, 398, 398, 404-406, 408 pattern recognition visual cortical neuron role, 643, 647 Pavlovian conditioning, see conditioning, classical peptidyl transfer in protein synthesis, 921, 923 perception, 302, 303-316 ambiguity of perceived modality, 314 analysis by synthesis, 314 brain correlates, 303-315 brain function and, 302, 303-315 brain lesions and, 305 as conscious experience, neural correlates for, 310. 315 development, 184 see also cognitive development evaluation criteria for sensory input, 310 "feature detectors" of, 306-308 feedback in, 312 of form, 310 functional approach to, 305 hierarchic neural structure for, 313ff just noticeable difference (JND), 303, 315 levels, 313-314 "matching response" mechanism, 306, 306, 312-314 "motion detectors," 308 of movement, by insects, 501-502, 509 neural representation, 306 readiness state and, 305, 313 stability of perceived world, 306, 308, 310, 310 structural inhomogeneity and, 309 van Holst's "cancellation" model, 310, 310 see also auditory perception; cognition; depth perception; form perception; perceptual anomalies; speech perception; visual perception perception, visual, see depth perception; visual perception perceptual anomalies, 304-305 ambiguity of perceived modality, 314 auditory contrast enhancement, 304 brain lesions and, 305 hallucination, 366 lateral inhibition and, 304, 305 neural information processing and, 304-305 motion without displacement, 308 phosphenes, 366 retinal rivalry, 308 simultaneous stimulation and, 304 superimposed sights, 366 visual pattern and motion, 311 see also optical illusions perceptual disorders, see cognitive disorders perceptual phenomena, 303 see also optical illusions perikaryal synthesis neurotransmitter storage and, 773 perineurium, 785, 786 peripheral nervous system, 73-82 amputation effects on, 76, 78 cellular composition of tissue, 84 cellular metabolism, effect on, 80, 81 CNS cell populations, effect on, 73-79 degradation in, 73-82 differentiation in, 73-82 nomenclature, 73 tissue culture, 84-91

peristalsis

1060 SUBJECT INDEX

in axonal flow, 847 peristimulus-time (PST) histograms, 649ff, 651, 659 permease protein, 704 permeation (membrane), 678 phage, see bacteriophage phasic control system, 415 phenotypic complexities, 953 phenylethanolamine-N-methyl transferase (PNMT), 532, 532, 533 ACTH effect on, 533 hypophysectomy effect on, 533 phenylketonuria (PKU), 189-190 pheromone, 511 degradation, 517 sexual attractant, 512 see also bombykol; odorants phospholipids in membrane, 704 vesicles of, 680, 680 photic stimulation, 342-343, 343, 344 photoreceptors, see rhabdomeres phylogenetic comparison, 30-37 behavioral plasticity, 34-35, 35, 36 L-ascorbic acid synthesis, 31ff, 33 vertebrate brains, 30-31, 31, 32 phylogenetic scale defined, 27 phylogenetic tree defined, 27 phylogeny primates, 30, 40ff, 42-46 vertebrates, 27-30, 28, 29, 30 see also evolution phytohemagglutinin (PPHA), 822-823 nerve growth factor (NGF) similarities, 822 RNA synthesis and, 822-823 Piaget, Jean cognitive development theory, 179-181, 290ff pigeon auditory conduction pathways, 23 brain, 15 forebrain, 20 see also avian brain pineal organ, 532ff, 536, 537 hypophysiotrophic factors in CNS control, melatonin synthesis in, 534, 535 serotonin synthesis in, 534, 535 pinealocytes, 532 as neuroendocrine transducers, 534, 535 pinocytosis, 725 pituitary gland, 530 plasmalemma, see cell membrane plasticity Aplysia neurons, 266-267 in autonomic nervous system, 218-222, 260-271 behavioral, 167-297 determinants of, 161-297 environment and, 289-294 evolutionary trends, 34ff, 36 heredity and, 289-294 of motivational systems, 207-208ff of nervous system, 161-297, 660 of networks, 489 pacemaker neurons, 266-267, 268, 269 respiratory centers, 265-266 synaptic, 740-742 at unitary level, 260-271 see also learning set; stability

PNMT, see phenylethanolamine-N-methyl transferase polymerase, RNA-dependent, 932, 932 polymorphism, 964, 970 polynucleotide chains annealing, 981ff complementary, 988 polypeptide chains, 887ff amino acid sequences, 888, 889, 889, 890, 891, 892 polysaccharides interneuronal synaptic relationships and, 747ff, 757-758 in retina, 757 Pongidae, see apes (Pongidae) positive feedback network, 398 in decapod crustaceans, 398 in Tritonia, 398 postsynaptic adhesions, 761, 762 of synaptosomes, 761, 762 postsynaptic discharge, 577, 578 postsynaptic inhibition, 440 postsynaptic potential (PSP), 459ff, 577-578, 582 patterns, 459 shape differences, 648-649, 652 spike generation probabilities and, 574 postsynaptic potential (PSP) trains, see spike trains potential divider effect in olfactory bulb, 555 PPHA, see phytohemagglutinin prechordal plate, 62 predication, 368-369, 369 presque vu phenomenon, 366 see also cognitive disorders presynaptic disinhibition, 433, 440 presynaptic facilitation, 264 presynaptic inhibition, 433, 440 presynaptic membrane catecholamines in, 326 presynaptic terminals, 578ff discharge rates, 578ff, 579 presynaptic vesicles amine storage, 325, 326, 326 neurotransmitter synthesis in, 325 primary memory, see memory, primary primates behavioral evolution, 39-47 hind-limb map, 606-608, 607 language communication, 45 neonate behavior (nonhuman), 351-352 phylogeny, 30, 40ff, 42-46 social communication, 357 socialization, 352, 359 spinal cord ontogeny, 130 tactile-kinesthetic system, 605-606 see also apes; evolution, primate; man; monkey problem solving in CNS, 382 progesterone, 531 prokaryotes defined, 998 DNA in, 1005 eukaryotes and, 873, 974, 999 gene conversion in, 970 gene expression in, 884, 980, 962-963 mutation rate in, 977, 977 prophage, 956, 959, 960 DNA ends, 957, 958 insertion-excision system in, 960

proportional error servomechanism in grasshopper flight control, 405-406 proprioceptive feedback, 404, 408 in grasshopper flight control, 405 in grasshopper leg control, 407 proprioceptive reflex, 54 protein, 883 axoplasmic transport, 851 binding, 904, 907 chain elongation factors in, 923 changes in learning, 278-289 in eukaryotic organisms, 883-884 factors, of ribosomes, 922 gene expression and, 883, 884 hydrogen-bonding groups in, 902, 903, 903, 907 initiation factors of, 923-924 interaction, 901ff membrane binding sites, 704 membrane, transport, 704, 704 in membranes, developmental changes, 815, 816 in mitochondria, 829 in myelin, 816 neural excitation, role in, 296 in neuroglia, 278ff noncovalent forces affecting conformation of, 901 nucleic acid interaction, 901-912 packing geometry, 902-904, 907 release from synaptic vesicles, 326 repressors, 884 role in chromosomal organization, 1010 sensory conditioning, changes during, 286-287, 287, 288 structure, 896-897 structure-function relationships, 883 transport, function of, 856 see also glycoprotein; immunoglobulin protein, acidic, 279ff, 287 in brain, 815-816 protein, antigen-alpha, 815 protein, Bence-Jones, 890, 896, 897 protein, neuronal, 278ff amino acid compositions, 855, 855 radioisotopic analysis, 843, 844, 846 protein, permease, 704 protein, soluble brain-specific, 278-279, 755 S100 protein, 278, 279, 815-816 antiserum, learning impaired by, 285-286, 286, 287, 295-296 learning and, 295 synthesis during learning, 285-286, 285, 288 14-3-2 protein, 815-816 protein synthesis in Acetabularia, 842 altered, during training, 281-285 acetoxycycloheximide inhibition of, 272ff, 272, 273 axonal, 815, 843 chain elongation factors in, 923, 924 cycloheximide inhibition, 273, 273 cytoplasmic, 828 dissociation factor in, 923, 924, 924 during learning, method for tracing, 281-283, 283 in explants, 843 hormone stimulation of, 333 inhibitors, 874 initiation factors in, 923, 924, 924

learning and, 295, 333, 823 memory and, 272ff, 272, 275, 277, 294-295 mitochondrial, 813-814, 813, 828, 829, 835 neuronal, 86, 841, 842, 843, 844, 845 neuronal, endoplasmic reticulum and, 808 neuronal behavior and, 883 peptidyl transfer in, 921, 923 rate of, 841 recognition in, 921 ribosomal, 812-813, 813 in Schwann cells, 844 sites of, 812 synaptic, neuron activity and, 330-331, 332 synaptosomal, 813, 814-815 two-site model for, 921, 921 psychological functions complex, 301-371 psychological stress EEG index of, 238, 239 EEG patterns during, 236-239 PSP see postsynaptic potential (PSP) PST (peristimulus-time) histogram, see peristimulus-time (PST) histogram psychology, see behavior theory; child psychology; comparative psychology; organismic psychology; stimulus response (S-R) theories of behavior psychophysiology neurosciences and, 303-304, 314-315 perceptual, 303-304 see also Fechner's law; Weber's law psychosexual differentiation, 196ff pulvinar glomerular synapses in, 435, 436, 441 punctured symmetry of olfactory bulb, 555 Purkinje cells activation of, 418 climbing fibers and, 409, 410, 414-415 dendrites of, 69, 413, 415-416, 419, 421, 422, 422 disfacilitation in, 423 in elasmobranchs, 418 extracellular recordings of, 414, 416 lateral inhibition in, 394 in mammals, 423 maturation, 105 mossy fibers and, 411, 429 neuronal connectivities, 415 parallel fibers and, 415-416, 440 schematic drawing of, 417 sequential activation of, 416, 418, 419 soma of, 411 synapses with, 413, 416 in teleosts, 420, 422, 422 transverse integration, 420-422, 422, 423 vertical integration, 420, 422, 422, 423 puromycin information retrieval, effects on, 275 retrograde amnesic effects, 274, 275 putamen, 465 pyramidal cells, 65, 448-449, 464-465, 464 focusing, 450 output biasing, 449-450 Q

Q\$\beta replicase kinetics of, 934 properties of, 933ff response to templates, 933, 934

sedimentation analysis of, 934 template specificity and, 932ff, 933 transfer experiments, 938ff, 938, 939 synthesis of, 933ff, 938, 939, 943ff

R

rabbit, 539ff diagram of head, 540 olfactory bulb, 542, 549 radiations, optic, see optic radiations radioactive labeling of neurons, 64ff, 66, 68, 69 see also radioisotopic analysis; thymidine-14C; thymidine-3H radioactive time scales, 41 radioisotopic analysis of neuronal protein, 843, 844, 846 see also radioactive labeling; thymidine-14C; thymidine-3H rage norepinephrine and, 327 Ramón y Cajal, S. neuron connection theory, 123ff, 136 Rana pipiens, see frog rat forebrain, 19 neuraland photic regulation of melatonin synthesis in, 534, 535 norepinephrine in, 773 social behavior, 42 readiness perception and, 305, 310, 313 readout system, 414 recall, see information retrieval recent memory, see memory, recent reciprocal inhibition network, 398, 398, 399 in Mauthner neurons of fish, 398, 398 receptive field on cortical map of somatosensory area I, 606, 608, 609 cutaneous nerves, 153 hind limb, 606, 608, 609 inhibition effects, 492 patterns, 609ff, 612 skin graft, reinnervated, 153 visual cortex, 318, 318 receptive field, visual alignment, 478, 479ff binocular stimulus specificities, 476-477 complex, 483-484 complex units, binocular responses, 483-484, 483 complex units, specificities of, 483ff inhibitory regions, 474, 475, 476 monocular stimulus specificities, 474-476 organization, 472-473 simple cells, binocular stimulus specificities, 476-477 simple cells, monocular stimulus specificities, 474-476 subliminal excitation zones, 474 receptive field disparity (vision), 477-478, 477 depth perception, role in, 477-478 see also retinal disparity receptors antennal, 512 firing rate and activity level, 666 reciprocal inhibition, 393 recognition molecular, 883-1013

interneuronal, 747-760 in protein synthesis, 901 systems, DNA-protein, 955ff recognition, perceptual, see cognition recognition sequences in E. coli and bacteriophage lambda DNA, 958, 959, 960 recognition systems DNA-protein, 955-962 rectification, 973, 979, 994, 995, 995 recurrent inhibition in olfactory bulb, 548, 548, 549 reeler mouse brain development, 104 cell alignment, 106 reflex arm flexion, 132 carotid, 54 conditioned, 261, 262, 264 cutaneous, onset of local, 132, 134 development, 133 knee-jerk, 293 local, onset of, 132-133, 133 misdirected in frog, 117-118, 120, 121 in rotated skin graft in frog, 117-118, 120, 121, 153 synaptogenesis and, 132-133 wiping, 153 regeneration, neuronal, 840, 843 reinforcement of motor patterns, 215 of self-stimulated behavior, 213-214 stimulus-bound behavior and, 214-216, 215, 216 of visceral response, 218, 219-220 remote memory, see memory, remote renin, 531, 532 Renshaw pathway, 544, 546, 548, 549 repetitious DNA, see DNA, repetitious replication of DNA, 1001, 1083, 1005-1010 of eukaryotic chromosomes, 998-1013 of molecules, 927-945 of RNA, 935, 939, 939, 940, 940, 941, 941 replication, "self-instructive' "living and nonliving," 928, 929 replicase, RNA, 931 MS2, 931ff, 931 sedimentation analysis and, 934 template specificity and, 931ff, 932, 934 repressors affinity for operators, 950-951 binding and, 949ff and genetic control, 950-951 lac. 949ff. 950 lambda, *950* nature of, 948ff reptiles behavior patterns, 339 phylogeny, 29 social signals, 350, 350 resolution in fly's compound eye, 504, 505, 509 respiratory centers assimilation of rhythms, 266, 267 plastic changes in, 265-266 respondent behavior, see stimulus-bound behavior reticular formation functions, 17 morphology, 16

1062 SUBJECT INDEX

sensory pathways, 16-17 reticulocortical activation, 462 retina cat, 630ff, 633ff cell specification, 756ff, 757 dendrites of a cone, 390 functional organization, 631ff, 631 ganglion cells of, 632ff, 633ff intracentral connection, 59 lateral inhibition effects, 636-637 neural circuit interactions, 394 neuron differentiation sequence, 139 optic tectum, neuron connections to, 120-122, 123, 124 polysaccharides in, 757 schema of, 630 sensitivity, Weber's law and, 638, 638 tectum connections, 756, 757 see also eye; ganglia, retinal; visual system retinal disparity, 471, 472 see also receptive field disparity (vision) retinotectal system carbohydrates in, 757, 757 interneuronal recognition in, 756-758 polysaccharides and, 757-758 retrograde amnesia, see amnesia, retrograde retrohippocampal formation neurogenesis, 65 rhabdomeres angular sensitivity distributions, 496, 509 arrangement of in upper eye, 496 dichroic absorption properties, 497, 498 of fly, 494–501, 496, 505, 508, 509 spectral sensitivities, 494-497 rhinencephalon, see limbic system rhombencephalon homology, 10 neuromeres, 69 sensory mechanisms, 9, 13-14 rhythm assimilation, 264 in respiratory centers, 266, 267 by Aplysia, 266-267, 268 rhythmic potentials in olfactory bulb, 549 ribonuclease catalytic action of, 910 interaction with nucleotides, 907, 907, 908, 908, 909, 909, 910, 911 packing geometry of, 905 pancreatic, 905 structure, 905, 905, 906, 906, 907 robonuclease-A, 905 ribonuclease-S, 905 cleavage, 905 interactions, 907, 908 structure, 905, 906 ribosomal RNA, see RNA, ribosomal ribosomes action of, 920-927 altered by mutation, 915, 916, 916 antibiotics actions on, 923, 923 assembly of, 913-920 dissociation factor, 924 of E. coli, 913ff, 913 functional analysis of 16S RNA, 917, 918 functional analysis of 30S proteins, 916, 917, 917 gross structure and function, 913, 913, 914 initiation by subunits, 922, 924 in vivo assembly of, 918, 919 mammalian, 925

mitochondrial, 828 mutationally altered, 915-916 neuroglial, 813 protein composition, 916ff protein factors, 922 protein synthesis in, 812-813, 813, 921ff, 921 reconstitution, 922 runoff, 924 streptomycin resistance, 915, 916 structure and function, 913-914, 921, 922 subunit assembly defective mutants (sad mutants), 919 30S assembly in vitro, 918 30S subunit, 913, *917*, 922, 923, 924, 925 30S subunit reconstitution from RNA and proteins, 914, 914, 915, 915 50S subunit, 913, 919, 922, 924, 925, 926 70S, 922 Ricco's law, 632 ritualization, 349-350, 351, 351 RNA eukaryotic genome and, 884 evolution of, 930 genes per genome in, 989 infectious viral, 936ff molecules, 938ff mutants, 937ff, 938, 938 polymerase, 947ff self-duplicating, 937-938 self-instructive replication, 938, 939, 939, 940, 940 sensory stimulation, changes during, 823 species, 989, 989 transfer from glia to neuron, 287 variants, 939ff, 939, 940, 942, 942, 943, 943, 944, 944 viral, 931ff mRNA (messenger RNA), 920, 921 degradation, 921, 922 formation, 922 transcription, 820, 921, 922 translation, 921, 922 RNA, mitochondrial, 828, 829 gene products of, 829 Q^β, RNA, 934, 934, 942ff replicase activity in, 934 response to different, 933 transfers and, 942ff, 942 RNA, neuronal synthesis, 81, 86 RNA, ribosomal, 828, 963, 964, 965, 966, 970, 989, *989* 16S, analysis of, 917 precursor, 990 transcription, 989 5S RNA, 989, 989, 995 30S RNA(subunit), 913ff, 914, 915, 916, 917 50S RNA(subunit), 913ff RNA synthesis, 946ff infectious viral, 936ff, 936, 937 kinetics, 934ff, 934-935 messenger, 947 tRNA (transfer) aminoacyl-, 921ff codon requirement for, 922 and DNA repetition, 964 genes in, 966, 989, 989 initiating, 922 in mitochondria, 922 polypeptide relationship, 920 RNA, viral, 936ff

communication of, 930-931 and enzyme responses, 934 formation of, 936, 937 and host cell, 930-931 radioactivity and, 937 replicase for, 931-933 synthesis of, 936-937, 936, 937, 943-944 transfer experiments, 939ff, 939, 940, 941 RNA replicase activity kinetics 932ff, 934 MS 2 as, 931ff purified, 934 Qβ as, 932ff, 938, 939 template saturation of, 934 and template specificity, 931-933, 932-933 and viral RNA, 931 of bacteriophage, 931, 932, 933 template specificity, 931, 932, 932, 933, 933 RNA synthesis, 933ff actinomycin-D inhibition, 820-821, 822 kinetics, 935 nerve growth factor (NGF) and, 821-822, 822 phytohemagglutinin (PPHA) and, 822-823 and viral RNA, 935-937, 936, 937, 941, 941

S

salamander (Ambystoma) motility, embryonic, 141, 148, 149, 150 mytotypic respecification, 153-154, 155 transplanted limb, 112, 153-154 saltations, 376-378 "sameness" neurons, 378-379 sarcoplasm membrane fluidity, 701 Saimiri sciureus, see squirrel monkey satellite cells, 84 Schwann cells axons and, 112, 786 birefringence and, 711 cytotypic maturation and, 84 derivation, 62 destruction in culture, 782, 782fn generation cycle, 63 intercellular clefts, 784ff, 786 location in culture, 89, 92 myelin and, 842 nerve fibers and, 783 nerve regeneration and, 112 nodes of Ranvier and, 722 oligodendrocyte pulsatility in, 91 organotypic maturation and, 84 in peripheral nervous system, 788 protein synthesis in, 844 selectivity, 59 surface membrane complexes of, 716 in vitro, 85-86, 847 see also myelin sheath; neurilemma; neuroglia; spindle cells secondary memory, see memory, secondary second signal system, 183, 184 see also cognitive development; language selective antibody response, 887, 887, 888 self-assembling neural nets, see neural networks, self-assembling self-duplication defined, 928 gene and, 927, 928 self-inhibition of mitral cells, 562 self-instructive replication, see replication, self-
instructive self-preservation affects of, 338 learning role, 193 neural mechanisms, 340 see also adaptive behavior self-stimulation, 210 duration, 214 in embryos, 143, 150 reinforcement of stimulus-bound behavior and, 213-214 sensation, 317 see also perception sensillum liquor, 513, 513, 514 sensory filter, 397, 408 in grasshopper wing stretch receptors, 404 in Limulus eye, 399 sensory ganglia, see ganglia, spinal (sensory) sensory input electrical activity of spinal cord, 146 in embryonic motility, 143, 144 role of, 215-216, 216 sensory memory, see memory, sensory sensory neuron differentiation, 131, 132 information transmission, 573 specificity, 59 see also nerve fiber connections; neural circuitry sensory pathway, 13-16 nonmammalian vertebrate, 9 nonspecific activating nervous system and, 377 see also nerve pathway sensory physiology methodology, 494 sensory relay nuclei glomerular synapses in, 440-441 see also medial geniculate body; lateral geniculate body; ventralis posterolateralis sensory signals neuronal response to, 598, 598 spike-train transmission and distortion, 597-604 sensory stimulation RNA changes during, 823 sensory systems, 9, 13-17 parallel, 377 septum classical conditioning, role in, 346 electrical stimulation, 346, 347 EPSPs in monkey and, 346, 347 phylogeny, 340 sequence-specificity in bacteriophage DNA ends, 956 serotonin behavior, role in, 329 biosynthesis in mammalian pineal organ, 534 central nervous system, distribution in, 327 distribution, 771 fluorescence, 327 in limbic system, 340 pineal function and, 535 sleep production and, 329 set (psychological) "attention" set, EEG patterns, 230 duration, 228 sex-related behavior testosterone effects on, 201-205, 202, 203, 204 sexual attractant insect, 511-518 see also pheromone sexual behavior, 196-207

gonadectomy effects, 198-199, 198 hormonal influences on development, 196ff mounting, 201ff, 204 social experience and, 201, 204 testosterone effects on, 200 see also lordosis reflex sexual development anhormonal, 198-199 genetic disorders, 196, 197ff, 200 hormonal influences, 196ff perinatal testis influence, 198-199 social experience and, 201, 204 testosterone effects on, 200, 205 sham rage, 208 short-axoned cells, see stellate cells short-term memory, see memory, short-term signal-to-noise ratio in fly's compound eye, 499, 499, 500 simple nervous systems, see nervous system single quantum effects in fly's compound eye, 498, 499, 499, 509 silk moth (Bombyx mori), 511-517, 513 antenna, 513 antenna, axon fusion, 513 chemoreception, 514, 515 electroantennogram (EAG), 512 olfactory receptors, 511-514, 515 sensillum trichodium, 513-514, 513 sex attractant system, 512, 517 single-cell response in, 514-516 simultagnosia, 366 simultaneous contrast, 304, 305 sinusoidal oscillator, one-Hertz, 387 skin grafts dorsoventrally reversed, 153ff in frog, 119-122 receptive fields, 118, 119, 122, 153 reflex development, 117-118, 120, 121, 153 reinnervation, 117-118, 119, 121, 122 rotated, 153ff size, 118 wiping reflex and, 153 see also cutaneous nerves; frog slave genes, see gene, slave sleep EEG amplitude distribution during, 226, 227 snake venom nerve growth factor (NGF) in, 819, 820 social behavior dominance, 356-357, 358 gonadectomy effects on, 201, 204 in Iguana, 350 in monkeys, 350-359 phylogenetic aspects of, 349-351 play, 202-203 ritualization, 349-350, 351, 351 septum and, 340 streotyped, evolutionary aspects, 339 sexual differences, 201, 204 see also social signals strategies of control, 356-357, 356 see also male social behavior; social communication; social signals; squirrel monkey social communication, 302, 349 animal, 349-359 between partners, 355-357, 355, 356 determinants, 358-359 information theory and, 355-357 innate and learned components, 352, 357-358 nonverbal in man, 357-358, 358 ontogenetic aspects, 351-352

perceptual analysis by synthesis and, 314 phylogenetic aspects, 349-351, 359 primate, 357 ritualization, 349-350, 351, 351 see also behavior, information theory and; language social signals auditory, response to, 358-359 back-rolling, 350, 351 electrical brain stimulation analysis, 355 gaze, 357-358, 358, 359 genital display in monkeys, 351, 351, 352 head-nodding of lizards, 350, 350 nonverbal in man, 357-358, 358 ontogenetic aspects, 351-352 visual signals, response to, 358-359 vocalization, 350, 352-353, 353, 354, 359 see also ritualization; social behavior; social communication social skills chimpanzees, 43 Society for Neuroscience, vi solvation free energy, alkali ion and, 687, 687 somatic afferent pathway, 605-617 somatosensorv area I cortical map, peripheral stimulus configuration, 613, 614 hind-limb representation in, 606ff, 608, 609 microelectrode penetration through, 606, 607 topology, 608-611 somatosensory area II cortical mapping in, 615 somatosensory mapping, see cortical mapping somatosensory projection, 606, 608 dermatomal trajectory role, 609-611, 611, 613, 614 see also cortical mapping somatosensory spaces abstract mapping and, 613-615 somesthetic systems, 377 species-typical behavior hypothalamic stimulation and, 213, 214 specificity in binding, 901-912 defined, 902 kinetic, 902 in lysozyme-inhibitor complexes, 904 neuronal. 62 in ribonuclease-nucleotide interaction, 907 of RNA replicase, 931-933, 931-933 static, 902 spectral analysis of spike trains, 592, 594-596 spectral sensitivities of rhabdomeres, 496, 497, 509 speech brain mechanisms, 363 cerebral representation, 357 control of behavior by, 183 language knowledge and, 364, 365 motor coordination for, 363 peri-aqueductal gray, 363 speech disorders anarthria, 363ff cortical topography and, 362 symptoms, 364 see also language disorders speech perception, 314 analysis by synthesis, 314 see also auditory perception

speech praxia defined, 365 spike duration, calcium level of membrane and, 707-708 latency, prediction of, 244, 245 probability-predicted, 244-248, 247, 247 prolongation, 707 shape-sorting methods, 648-649, 650, 654 in visual cortex, 246 waveforms, 649, 650 see also firing; neural conduction spike potential, 598 discharge, cross-correlation with, 580 generating probabilities, 574, 574 generation, 581-583 information transfer by, 597ff presynaptic discharge and, 574 spike shapes sorting of, 650 spike trains analysis of, 649ff, 661ff analysis techniques, 389 autocorrelation of intervals, 590 autocovariance, 594 axon filtering, 377 codes, variety of, 587-590 communication channel probabilities and, 598-599, 598 comparison of simultaneously observed, 591-594 cross-correlation histograms, 591-592, 592 data transmission by, 661-671 density, information transmission and, 600-601 demodulated, 664ff, 664 firing times, 665ff, 666, 667 Fourier transform, analysis by, 592, 595-596 functional interaction categories, 652-660 impulse frequency and information transmission, 662-663 information-carrying parameter, 662-663, 663 information transmission, role in, 587-596, 597-604 input patterns and, 578, 579 input rates and, 576, 577-578 instantaneous frequency, 662 interspike intervals, 570-571 interval codes, 588ff, 589 interval histogram, 590 joint peri-stimulus-time histogram, 652, 659 low-pass filter in, 665, 666 measurement, 572-573 measurement, descriptive statistics, 649, 651-652 neural codes in, 587-588 neuron as analyzer of, 577-582 neuronal analysis, 577 neuronal response and, 598-599, 598 random, power spectrum of, 668, 669 rate codes, 588ff, 589 regular rates, effects on single-channel transmission, 666-668, 668 sensory signals and, 597-604 serial correlogram of intervals, 590-591 spectral analysis of, 594-596 spike intervals, 662, 666 statistical measures for, 590-596 time intervals, measurement, 651-652 see also firing pattern; neural codes spin labels, 697ff, 869 amphiphilic labels, 698, 700, 701

anisotrophic motions, 700-701 Hamiltonian, 698 motions in membranes, 698, 700ff nitroxide free radicals, 697 nitroxide group, paramagnetic resonance, 698, 700 orientation, 698, 700, 701 paramagnetic resonance spectra, 698, 699, 700, 700.701 Pauling-Corey-Koltun model, 698, 699, 702 see also TEMPO spinal cord brachial enlargement, 109 central canal, 58 conduction pathways, 17-18 deafferentation, in chick embryo, 143-144, 143, 144, 147 development of, 136-139, 139 electrical activity, in embryo, 144-147, 146 embryonic, 144, 147 limb movement, role in, 154 lumbar enlargement, 109 mechanisms, intrinsic, 10 mechanisms, sensory, 9, 13-14 morphogenesis, 58 motor column differentiation, 109 ontogeny, 130-136 primate ontogeny, 130 somatotopic representation, 154 synaptic connections, 130 spindle cells, 64, 84, 88, 90 migration, in vitro, 85 in spinal ganglia, 86, 88, 90 ventricular zone, orientation, 64 see also fibrocytes; Schwann cells spinocerebellar pathway, dorsal neuronal signal transmission in, 617-629 split-brain studies, 322 spongioblasts germinal cell origin, 63 see also neural tube squid axoplasm, 855, *855* squirrel monkey (Saimiri sciureus) back-rolling, 350, 351 dominance behavior, 356-357 genital display, 351, 351, 352 social signals, 350ff, 351 vocal repertoire, 352, 353, 359 stability, neurobehavioral, 162 learning and, 162 of motivation systems, 207-208ff see also plasticity statistical techniques autocorrelation of spike intervals, 590 autocorrelation of spike discharges of a neuron, 582, 582 autocovariance, 594 correlogram, 652 cross-correlation, 578, 580, 581, 591-592 cross-covariance, 595 cross-interval histogram, 651-652, 653, 654, 655 Fourier transform, 595-596 joint-peri-stimulus-time scatter diagram, 652, 659 serial correlogram, 590-591 spectral analysis, 592, 594-596 of spike-train analysis, 590-596 see also systems analysis stellate cells

lateral inhibition and, 419 morphology of, 411 as part of module, 449 origin of, 411, 413 stereopsis, see depth perception stereoscopic vision, see depth perception Steven's law, 303-304, 306 Stimulationsorganen defined, 404 stimulation, brain, see brain stimulation stimulation, visual contour analysis, 319ff, 319 global features, 318 locus-specific analysis, 319-321, 319, 322 spatially distributed processing, 317-323 stimulus-response (S-R) theories of behavior, 177ff, 185 concept formation, 177 habit-family hierarchy, 178 hierarchical organization of performance, 177-178 language and, 177, 178 reversal shift, 177 verbal mediation, 177 stimulus, sensory emotional state and novelty, 330 genetically significant, 330 stimulus persistence, 165-166 stimulus-bound behavior, 208, 214 drinking, 210ff drive state and, 210 eating, 210ff electrode size and, 210 electrolytic brain lesions and, 211-213 environmental conditions and, 214 hypothalamic site and, 209ff, 211, 212, 213, 215 modifiability, 208-211, 209 prepotent responses, 213-214, 215 reinforcement of, 214, 215-216, 215, 216 stimulus duration and, 214 see also electrical brain stimulation stimulus-response matrices, 571, 573, 573 streptomycin resistance of mutationally altered ribosomes, 915, 916 stress, see psychological stress striate cortex binocular receptive fields of neurons, 476-477 neurons, classification of, 473 receptive fields of single neurons in, 472 retinocerebral fibers in, 472 subcellular fractionation, 761-764, 763 subjectivity, 336, 337 see also affect; individuality submaxillary gland 7S nerve-growth factor in, 817ff substantia gelatinosa synaptic complexes in, 438, 439, 440-441 subsystem defined, 486ff thalamic cortical, 427-443 see also neural subsystems subventricular zone glial cell, formation of, 69 supraoptic hypothalamic nuclei, 532 symmetry of mitral cell population 555, 555 synapse adrenocortical hormones and, 333 apparatus, 871 amine release and, 331

chemical transmission at, 715-720 cholinergic terminal of, 764ff, 786ff, 770, 773, 775 circuitry development in, 134, 135 classification of, 739-740 cleft material, 761-762 closure, sequence of, 132-136, 132 connections, formation of, 740-741 consolidation of, 261-262, 262, 263 differentiation rate, 134 electrical activity of, 715ff, 718, 719, 768ff end-plate potentials and, 775 electron coupling, 721-722 "epoxy theory" of consolidation, 262-263 E-PTA staining, 735-738, 737, 740 excitatory and inhibitory, 723-724 glycoproteins and, 747ff, 752-756 information storage by, 261-264 information-transmitting capacity, 572 interactions, 263-264 investigation techniques, 761ff, 763 juxtamembranal specializations, 724-726 link development, 104ff, 132-136, 132 linkage sequence, 132, 134 membrane complexes at, 715ff molecular biology of, 676, 715-782 molecular transfer at, 872 morphological features, 738 neuroplasmic flow and, 873 nomenclature, 771 number of, 739 plasticity of, 740-742, 862, 864 polysaccharides and, 747ff postsynaptic structures, 739 presynaptic microstructure, 739 release mechanisms in, 872 retinal ganglion cells and, 757, 757 specializations in, 724, 724, 735-739 staining techniques for, 722 structures at, 870-872 subcellular structure and, 762 transmission, invertebrate, at, 720-721, 769ff transmission structures at, 715 transmission, vertebrate, at, 721-722 transmitter release mechanisms at, 776ff, 777, 778.872-873 transposition, 741 ultrastructure of, 715-728, 729-747, 870-873 "unspecific afferents" and, 331, 333 variations in. 740 vesicles at, 723, 724ff, 724, 725, 729ff, 730, 731, 733, 737, 738 see also motor end plate; polysaccharides; synapse, adrenergic, 326 amine storage, 326, 326 endocrine-cell innervation and, 520, 522 neurotransmitter at, 325 neurotransmitter inactivation at, 778 synapse, axo-axonic, 440, 441 in LGB glomeruli, 433 presynaptic inhibition in, 433 in substantia gelatinosa, 438 in VPL glomeruli, 433 synapse, axodendritic in substantia gelatinosa, 438 synapse, cholinergic neurotransmitter inactivation at, 778 organization, 764-766 synapse, dendrodendritic, 552-565 graded activation, 563 in olfactory bulb, 541, 546, 546, 547

synapse, excitatory cerebellar glomerulus as, 429 morphological features, 723-724 synapse, glomerular, 427-443 in lateral geniculate body, 431, 433, 433, 435, 441 in lateralis posterior nuclear group of thalamus, 435 in medial geniculate body, 433 operation of, 427-443 in pulvinar, 435, 441 in sensory relay nuclei, 440-441 in ventralis posterolateralis, 433, 440 see also synaptic complex synapse, inhibitory cerebellar glomerulus and, 429 morphological features, 723-724 synapse, retinal specializations, 723, 723 synapse, retinotectal, 756 "synapse gap," 729, 742-743 synaptic activation, graded of dendrodendritic synapses, 563 synaptic apparatus, 870, 871-872 synaptic boutons, 715, 721 synaptic vesicles in, 723 synaptic bulb development rate, 137, 134ff in neuropil, 136, 137 reflex onset and, 133, 134, 135 synaptic cleft neurotransmitter in, 776 synaptosomes and, 761 synaptic complex in substantia gelatinosa, 438, 438, 440-441 see also synapse, glomerular synaptic coupling specificities of DSCT, 617-618 synaptic disk, 721, 721 synaptic function, 761-768 metabolic regulation, 864 synaptic junction, 411 density, maturation and, 738, 739 morphology, 739 "tight" junctions, 721-722 synaptic membrane morphological changes with electrical stimulation, 715-720, 717-719 osmiophilia, 718-719, 719, 720 synaptic membrane complex in crayfish ganglia, 716, 717-719 synaptic organization in visual system, 630-647 synaptic potential of motor neurons, 862, 863 synaptic receptors, 871 synaptic transmission in invertebrates, 720-721 in vertebrates, 721-723 see also neural transmission synaptic vesicles, 715ff, 729-735 acetylcholine in, 722-723, 725, 764, 771 catecholamine content, 732 differentiation of excitatory from inhibitory endings and, 724 derivation from interconnected tubular system, 725ff, 726 electron-lucent (agranular), 730-732, 731 electron-opaque (granular), 731, 732-735 esterase activity, 765-766 exocytosis and, 725

fixation, variations with, 734-735, 736 isolated, 726, 766 large granular (LGV), 733-734, 733 microtubule contacts, 875-876 neurotransmitter storage in, 730, 774 origin, 729 presynaptic densities, 724, 724 quantal release and, 725 in rat cerebellar cortex, 737 size, in terminal axons, 715, 724 small granular (SGV), 732-733, 732, 734-735 types of, 731 synaptogenesis 130-140 onset, 134 synaptoid configurations, 524, 524 release sites for neurohormones, 525 synaptoid vesicles, 525 synaptology, 715, 722-723 synaptosomes, 761ff leucine incorporation inhibited by antibiotics, 814, 814 as miniature cells, 761 protein synthesis in, 813, 814-815, 864 separation from myelin and glial fragments, 763 stability of, 763 synchrony of mitral cell population, 555, 555 syntax, 369 hierarchical organization, 178 systems components, 487ff general-purpose, 489 motivational, 207-217 simple cortical, 539-552, 552-565 special-purpose, 489 see also neural subsystems systems analysis, 375-383, 384, 395 abstract element, 384 functional context, 395 of neuronal functions, 378-382, 381 of neural transmission, 661-662, 669 signal context, 395 of social institutions, 380, 381 structural context, 395 see also information theory; neural subsystems Т tactile-kinesthetic system, 605-606, 613 tectum, see optic tectum teleology, 488 template specificity of RNA replicase, 931, 932, 932, 933. 933 TEMPO (tetramethylpiperidine-1-oxyl) paramagnetic resonance spectrum, 697-698, 697

Pauling-Corey-Koltun model, 698ff

in plasma of newborn rats, 198, 198

1066 SUBJECT INDEX

birefringence of nerve membrane, effect on, 712, 713 sodium conductance in nerve membrane and, 708, 709 texture inhomogeneous, visual adaptation to, 308, 309 thalamic-cortical desynchronization, 451-452, 468 EEG, 462, 462 by pontine-reticular stimulation, 463 by stimulation of medial thalamic nuclear complex, 451, 456 thalamic-cortical subsystems, 427-443 thalamic nuclei, 433, 435, 463 intralaminar, 464-465, 467 medial, 461-467 thalamic somatosensory relay, 444 thalamic synchronization, 450-451, 456, 460, 460, 461-462, 466, 468 filtering, 461 gating, 461-462, 468 thalamocortical relay, 443, 446, 448, 452 ventrobasal, 447, 454-455 thalamocortical sensory fiber, 455, 499 thalamopetal pathway, 445, 446 thalamopetal relay, 444, 448 thalamus, 443-456, 458-470 afferent systems in, 447 auditory system representation, 14 avian, 16 axonal trajectories in, 453 cell proliferation, 67ff cell systems, axonal trajectories, 452, 453 conjoint operations in, 468 dendrites in, 455 desynchronization in, 451-452, 461-462 glomeruli in, 433ff history of research on, 443-444 homology, 11, 14 interneuronal "interface," 465-468 internuclear reactions in, 463ff, 464, 465 intralaminar (nonspecific) system in, 449, 452, 455 modality in, 444-448, 458-460 moduli in, 449, 455 multiplexing in, 452-453, 456 neurogenesis, 65ff, 70 neuropil in, 447 nonspecific cell systems in, 452, 452, 453, 453 nonspecific output, 464-465, 465 operations of, conjoint, 468 organization of, 443 parallel processing in, 464-465 pathways in, 445 reciprocity of internuclear interactions in, 433, 463, 464 reflux of, 453-454 relay cells in, 433-438, 444ff, 445, 452ff subsystems, 443-456, 458-470 synchronization in, 450-451, 460-462 topographical specificity, 444-448, 458-460 ventroanterior nucleus, 465 ventrobasal neurons, 458-459, 459, 462, 464 ventrolateral neurons, 458, 461-464, 467, 467 ventrolateral nucleus, 465-466 vertebrate, 14 visual-system representation, 15-16 thymidine neuron incoporation of, 841 thymidine-14C, 1008, 1009 thymidine-3H, 1002, 1005, 1006, 1009

cell generation cycle, effects on, 64 cell migration analysis, 65, 66, 68 neuroglial formation analysis, 69 thyroid stimulating hormone (TSF), 531 thyroxine, 531, 532 time, memory and, 164 time scales. 41 timing device system, 415-416 tissue culture, see nerve tissue culture tissue, neural, see neural tissue toad (Xenopus) optic nerve connections, 120-124, 123, 124 optic-cup nuclei, 125 retina, cell differentiation, 122 retinotectal projection, 122, 123, 124 ventral-horn cells, 74-79, 75, 77, 78 tools, stone, 44 topology of body representation, 605-617, 609 topography, central, 109-110 language and, 362-363 transcription, 1003, 1005, 1010, 1011 of messenger RNA, 921, 922 of neuronal networks, 1011, 1012 of ribosomal RNA, 989 transducing phages, 958, 959, 959 transfer RNA, see tRNA (transfer) transformational grammar, 178, 368-369, 369 translation of messenger RNA, 921, 922 transport axoplasmic, 851-857 parallel, 703 perpendicular, membrane fluidity and, 701, 703-704, 705 of lactose, 704 see also axoplasmic transport; ion transport; neuroplasmic flow transposable control elements in genetic systems, 963 trial-and-error learning, 192-193 tritiated thymidine, see thymidine-3H triune brain, 336-349 tryptophan, 535 dibutryl-AMP effects on synthesis, 535, 535 tufted cells of olfactory bulb, 541, 546, 547 turkey courtship behavior, 41-42 Turner's syndrome, 197 two-stable-states theory, 707-708, 858 tyrosine, 325 norepinephrine synthesis from, 325, 325 sympathetic neural impulse and, 325, 325 tyrosine hydroxylase electroconvulsive shock in rat brain and, 328, 328 norepinephrine synthesis, role in, 325 U

ultrastructure synaptic, 715-728, 729-747 uncouplers mitochondria, effects in, 681 uniocular perception, see monocular vision urodeles limb muscle neurons, 154 limb transplant, 154 "motor path," 133 motor-system organization, 109, 110 muscle topography, 154 spinal cord, 154

V

vagus nerve membrane fluidity, 701 variants, RNA base ratio of, 942 diverse, isolated, 942-944 fast-growing, 939 isolation of, 944 replication in, 942 resistant, 943 synthesis of, 941, 941, 943 V-1, 939ff, 941 V-2, 940ff, 941 V-3, 943 V-4, 942ff V-6, 942, 943 V-8, 943 V-9, 943 vasopressin, 779, 779 venterolateral column, 109ff ventral horn amputation effects on development, 78, 78 astrocytes, 135 formation, 109 lumbar, living cells in, 75 urodele. 110 ventral-horn cell, 74-79 abundance, 74ff amputation effects on, 78, 78 astrocytes, 135 chromatolysis, 78 death, 78 degeneration, 77, 78-79 developmental phases of, 78, 79 endocrine action on, 78 injury, responses to, 809 ventralis posterolateralis (VPL) glomerular synapses in, 433, 440 ventricular cell ciliogenesis, 64 cilium, 64 fine structure, 63 generation cycle, 63-64 neuroblast retraction from limiting membranes, 70 neuroglial formation and, 69 nuclear migration, 63, 70 proliferation, regional analysis of, 64 transition to Phase I, 79 ventricular zone granule-cell origin, 65, 70 habenula programing by, 67 neuroglial origin, 69 nuclear migration, intermitotic, 63, 64 proliferative gradients in, 67-68 ventroanterior nuclei, 465ff ventrobasal cell matrix information updating in, 446 ventrolateral nuclei, 465ff intracellular recording, 466 thalamic input to, 467 ventrobasal nuclear complex, 445 verbal behavior EEG activity related to, 236-239, 237, 238 verbal communication, see speech; vocalization vertebrate brain evolution of, 7-26, 26-39, 32, 35 gross morphology of, 8-16, 12, 15, 19-24, 31-33

homology in, 18-22 motor system, 17-18 neuronal systems, 16-17 phylogeny, 30-37, 31-33 structure, 7-26 see also avian brain vertebrates brains, 30-31, 31 central neurons of, 798-811 evolution, 26-39, 28, 29, 30 embryonic motility, 141-151 motor-system development, 108-116 neural transmission in, 721-722 neural-tube origin, 62 neurons, 798ff, 800, 810 phylogeny, 27-37, 29 stereoscopic mechanisms human, 472 see also individual species vestibular memory, 264-265, 265 see also bacteriophage visceral learning, see learned visceral response vision central mechanisms of, 14-15 contour-specific, 319, 321 destriation effects, 322-323 eve movements and maturation, 184 figure-specific analysis, 321, 322 form, 471-485 locus-specific analysis, 318ff receptive field disparity, 477-478, 477 receptive fields, 472ff split-brain effects, 322 visual cortical ablation effects, 323 wedge-prism effects, 307, 320, 322 see also binocular vision; depth perception; monocular vision; retina; visual perception visual adaptation, 637-638 retinal sensitivity regulation due to, 637-638 visual cortex ablation effects on vision, 323 binocular connections, formation of, 126-127 directional movement sensitivity, 643, 646 EPSPs in. 642 functional organization, 643 intracellular analysis, 643, 644-646 monocular pattern deprivation effects, 323 optimal stimuli, 643, 644, 645, 646, 646, 647 receptive field formation, 318, 318 spike trains of cat in, 246, 251 synaptic organization, 642-643 visual fixation by fly, 505-509, 506, 507, 508 visual pathway, 377, 478 cerebral cortex function in, 377 midbrain tectum function in, 377 visual perception behavior and, 319-323 binocular, 476ff

brain function and, 303-316 color adaptation in contour detectors, 308 contour detectors and, 306-308 deprivation and, 321 de-striation effects, 322-323 EEG patterns of monkey during, 232-233, 233 evoked cortical response, 310, 312 "feature filters," 305, 308, 311-312 by fly, 505-509, *506*, *507*, *508* half prisms and, 321 of motion, 308, 311 monocular, 474ff "motion detectors," 308 nervous system and, 322 pattern analysis, 310, 311, 312, 323 pattern and motion, 308, 309 perturbation, 320 retinal rivalry, 308 sensory input and exploratory activity, 310 stability during voluntary eye movement, 310, 310 stroboscopic illumination effects, 308 of texture, 308, 309 visual noise, 306, 307, 309 von Holst's "cancellation" model, 310, 310 see also depth perception; form perception; optical illusions; simultaneous contrast visual rearrangement, 320-322, 321 adaptation to, 320-321, 322 visual receptors lateral inhibition, 389, 392 light shadow transitions on, model of, 392 visual transduction in, 393, 393 visual stimulation spatially distributed, 317-324 see also visual perception; visual system; visual cortex visual system avian, 20-22, 22 binocular connections in visual cortex, 126-127 Cartesian model, 317, 318, 318 convergence of neuron outputs, 317, 318, 318 CNS mechanism, 9, 11, 14-16 figure-specific information in, 322 Hubel and Wiesel model, 317, 318, 318 hierarchical processing in, 492 information processing, sequential, 473 lateral inhibition in, 394 locus-specific information in, 319, 322 neurogenesis, 120-123 neuron specification, 120ff neuronal connections, prefunctional development, 118-123 organization, stereopsis and, 472 receptive fields, 472ff retinal circuit interactions, 394 spatially distributed information in, 317ff specification of neuronal connections, 123-124

synaptic organization in, 630-646 thalamic representation, 15-16 see also eye; optic chiasma; optic nerve; optic tectum; retina; vision visual transduction processes, 391, 393 models of, 393 visual-motor coordination binocular deprivation effects, 321 locus-specific analysis and, 319-320, 320, 321 midbrain role, 323 modifiability in neonates, 321 monocular deprivation effects, 321 visual cortex ablation and, 323 vocal system homology, 357 vocal tract language capacity and, 363 vocalization of birds, 192 cerebral representation of, 353-354 electrical brain stimulation, elicited by, 353ff, 354.359 genital display in monkeys and, 354-355 of man, 356 of monkeys, 352-357, 353, 354 motivational state and, 352-353, 354, 359 peri-aqueductal gray, role in, 353, 363 as social signal, 350, 352-353, 354 see also social communication; speech Vygotsky, L.S. cognitive development theories, 183-184 language concepts, 184

FIGURE 7 A family of "ideal" curves representing the development of learning set in various animals. The curves were obtained by the fitting of smooth curves to empirical data points. The data of the human children and chimpanzees were from Hayes et al. (1953); those of the gorillas, from Fischer (1962); those of the rhesus monkeys, from Harlow (1959); those of the mangabeys, from Behar (1962); those of the squirrel monkeys, from Miles (1957); those of the marmosets, from Miles and Meyer (1956); those of the cebus monkeys and spider monkeys, from Shell and Riopelle (1958); those of the squirrels and rats, from Rollin, cited in Warren (1965); those of the ferrets, minks, skunks, and cats, from Doty et al. (1967); those of the tree shrews, from Leonard et al. (1966); and those of the pigeons, from Ziegler (1961). As the human, gorilla, and chimpanzee in studies each reported data on only two subjects, the curves of each subject are shown separately.

FIGURE 7 Effect of rhythmic intracellular stimulation of a burster cell (R15) of *Aplysia*. The average spontaneous burst interval is 67 seconds. Rhythmic intracellular depolarization is applied (black bars) six times, with an interstimulus interval of 56 seconds. After the end of the stimulation period,

FIGURE 1 Effect of acetoxycycloheximide on protein synthesis in the cerebrum and memory. Mice were injected subcutaneously with 240 μ g of acetoxycycloheximide 30 minutes before training to escape shock by choosing the lighted limb of a T-maze to a criterion of five out of six consecutive correct responses. Different groups were tested for retention (per cent savings) at each of the indicated times. (For details, see Barondes and Cohen, 1968a.)

FIGURE 8 Current sources and sinks calculated from the field potentials evoked by local stimulation of the surface of the cerebellar cortex in the alligator (*Caiman sclerops*). The field potentials were recorded simultaneously by an array of five microelectrodes (see photograph and diagram to the right). A shows a computer average of the fields produced by a set of eight successive local stimuli, each set administered at a different depth and recorded from electrode #5. Upward arrows represent stimulus artifacts. In B, current densities calculated from potentials recorded with the five microelectrodes at depths indicated to the left of each record. First downgoing arrow indicates current generated by the parallel-fiber volley; second arrow the current generated by the activation of parallel fiber and Purkinje cell. Upgoing transients indicate current sinks; downgoing arrows in B demonstrate that, after local stimulation, a

FIGURE 1 Cross section through an ommatidium of Musca. Seven sensory cells with their attached rhabdomeric structures are shown. The diameter of each of the peripheral rhabdomeres (1-6) is about twice that of the central one (7).

FIGURE 5 Electron micrograph of lampbrush chromosome loop. DNA duplex is the traverse thread; long RNA chains the first spontaneous burst appears after the entrained interstimulus interval. Maximal spontaneous variability of the mean interburst interval, 3.5 per cent. Induced change, 15 per cent.

> sink of current is generated and moves downward to the level of the soma. Note increase in latency of the current sink with depth. Time calibration as in D. In C and D, a series of field potentials recorded by electrode #5 after a weak stimulus to the cerebellar cortex. C was recorded immediately in line, and D was recorded 200μ out of beam. E and F show the current densities associated with the potentials shown in C and D. Note that the weak local stimulus is able to generate a dendritic sink which moves downward in time and which seems to move transversely so that in F a source-sink relation is generated which does not, however, invade antidromically but instead produces a dendritic current source at higher levels (see arrow at 200μ depth). Abbreviations: PC, Purkinje cell; ML, molecular layer. (From Llinás and Nicholson, 1969.)

Rhabdomere 8 cannot be seen in the Figure, as it is situated proximal to 7. Note the different orientations of the microvilli in the different rhabdomeres. Fixation: glutaraldehyde-osmium. (From C. B. Boschek, unpublished.)

extend from it. (Courtesy of O. L. Miller, Jr.)
